1. Introduction

The technical development of ultrashort laser pulses covering infrared to extreme ultraviolet has opened a door to study the photo-induced dynamic physical and chemical processes. By using an optical excitation at a particular wavelength, exotic states can be trigged coherently in atoms, molecules, clusters as well as complex condensed systems. The evolution of excited states then can be imaged in the real-time domain by subsequent single or trains of pulse. This laser pump-probe technique features an unprecedented spatial and temporal resolution, thus not only allows us a fundamental insight into the microscopic ultrafast dynamics, but also brings about a potential of selective controlling on the microstructures at atomic scale (Krausz & Ivanov, 2009).

In this chapter, a recent advance of soft x-ray laser speckle pump-probe measurement on barium titanate (BaTiO$_3$) is reviewed, with primary concerns on the theoretical description of the photo-matter interaction and photo-induced relaxation dynamics in the crystal. Here, the observed time-dependent speckle pattern is theoretically investigated as a correlated optical response to the pump and probe pulses. The scattering probability is calculated based on a model with coupled soft x-ray photon and ferroelectric phonon mode of BaTiO$_3$. It is found that the speckle variation is related with the relaxation dynamics of ferroelectric clusters created by the pump pulse. Additionally, a critical slowing down of cluster relaxation arises on decreasing temperature towards the paraelectric-ferroelectric transition temperature. Relation between the critical slowing down, local dipole fluctuation and crystal structure are revealed by a quantum Monte Carlo simulation.

This chapter is organized as follows. In Section 1, the properties ferroelectric material and experimental techniques are introduced. The theoretical model and methods are elaborated in Section 2. In Section 3, the numerical results on speckle correlation, relaxation dynamics
of polarization cluster and critical slowing down are discussed in details. In Section 4, a summary with conclusion is presented finally.

1.1 General properties of \( \text{BaTiO}_3 \)

As a prototype of the ferroelectric perovskite compounds, \( \text{BaTiO}_3 \) undergoes a transition from paraelectric cubic to ferroelectric tetragonal phase at Curie temperature \( T_c = 395 \) K. As schematically shown in Fig. 1, above \( T_c \), the geometric centers of the Ti\(^{4+} \), Ba\(^{2+} \) and O\(^{2-} \) ions coincide, giving rise to a non-polar lattice. Below \( T_c \), the unit cell is elongated along the \( c \) axis with a ratio \( c/a \approx 1.01 \). The Ti\(^{4+} \) and Ba\(^{2+} \) ions are displaced from their geometric centers with respect to the O\(^{2-} \) ions, to give a net polarity to the lattice. The formation of spontaneous polarization by the displacement of ions is along one of the [001] directions in the original cubic structure. Thus, below \( T_c \), there are two kinds of ferroelectric domain developed with mutually perpendicular polarization (Yin et al., 2006). The paraelectric-ferroelectric phase transition and domain induced static surface corrugation have been well resolved by the means of atomic force microscopy (Hamazaki et al., 1995), scanning probe microscopy (Pang et al., 1998), neutron scattering (Yamada et al., 1969), and polarizing optical microscopy (Mulvmill et al., 1996).

Fig. 1. The crystal structure of \( \text{BaTiO}_3 \) (a) below the Curie temperature the structure is tetragonal with Ba\(^{2+} \) and Ti\(^{4+} \) ions displaced relative to O\(^{2-} \) ions; (b) above the Curie temperature the cell is cubic.

Ferroelectric materials have a variety of functional capabilities in the electronic devices, which include non-volatile memory, high permittivity capacitor, actuator and insulator for field-effect transistor (Polla et al., 1998). Application of ferroelectric materials has attracted a great deal of attention in recent years to enhance the performance of implementation. This requires a comprehensive knowledge concerning the behaviours of ferroelectrics at the nanoscale, such as the roles of strain, depolarization fields, domain configurations and motions. Besides, there is also an increased demand to understand the mechanism of paraelectric-ferroelectric phase transition. In the case of \( \text{BaTiO}_3 \), it is generally considered that the transition is a classic displacive soft-mode type, which is driven by the anharmonic lattice dynamics (Harada et al., 1971; Migoni et al., 1976). However, recent studies have also suggested that there might be an order-disorder instability which coexists with the displacive transition (Zalar et al., 2003; Völkel & Müller, 2007), making this issue still controversial to date.

The nature of the phase transition is believed to be unveiled in the precursor phenomena. For \( \text{BaTiO}_3 \), this is the emergence of dipole fluctuations with regional uniform alignments,
Probing Ultrafast Dynamics of Polarization Clusters in BaTiO$_3$ by Pulsed Soft X-Ray Laser Speckle Technique

i.e. the polarization clusters (Takagi & Ishidate, 2000). While, it is still not clear how these polarization fluctuations condense into long range ferroelectric correlations as temperature decreases. Therefore, it is of great significance to directly observe the creation and evolution of polarization cluster in the vicinity of $T_c$.

1.2 Experimental methodology

Since the aforementioned conventional time-average-based measurements cannot be applied to detect the ultrafast transient status of dipole clusters, the diffraction speckle pattern of BaTiO$_3$ crystal captured by the picosecond soft x-ray laser has turned out to be an efficient way.

![Schematic diagram of soft x-ray speckle pump-probe spectroscopy system using a Michelson type delay pulse generator and a soft x-ray streak camera. All the optical components are set in a vacuum (~10$^{-4}$ Pa). The delay time of the second x-ray pulse from the first one can be manipulated by changing the delay path length between the beam splitter and x-ray mirror.]

Speckle is the random granular pattern produced when a coherent light is scattered off a rough surface. It carries information of the specimen surface, for the intensity and contrast of the speckle image vary with the roughness of surface being illuminated (May, 1977). Numerous approaches have been devised to identify surface profiles by either the speckle contrast or the speckle correlation method (Goodman, 2007). Recent application of pulsed soft x-ray laser has improved the temporal and spatial resolution to a scale of picosecond and nanometer. By this means, dynamics of surface polarization clusters of BaTiO$_3$ across the Curie temperature has been observed (Tai et al., 2002; Tai et al., 2004), which paves a new way to study the paraelectric-ferroelectric phase transition.
Very recently, Namikawa (Namikawa et al., 2009) study the polarization clusters in BaTiO$_3$ at above $T_c$ by the plasma-based x-ray laser speckle measurement in combination with the technique of pump probe spectroscopy. In this experiment, as shown in Fig. 2, two consecutive soft x-ray laser pulses with wavelength of 160 Å and an adjustable time difference are generated coherently by a Michelson type beam splitter (Kishimoto et al., 2010). After the photo excitation by the pump pulse, ferroelectric clusters of nano scale are created in the paraelectric BaTiO$_3$ and tends to be smeared out gradually on the way back to the equilibrium paraelectric state. This relaxation of cluster thus can be reflected in the variation of speckle intensity of the probe pulse as a function of its delay time from the first pulse. It has been observed that the intensity of speckle pattern decays as the delay time increases. Moreover, the decay rate also decreases upon approaching $T_c$, indicating a critical slowing down of the cluster relaxation time. Hence, by measuring the correlation between two soft x-ray laser pulses, the real time relaxation dynamics of polarization clusters in BaTiO$_3$ is clearly represented. In comparison with other time-resolved spectroscopic study on BaTiO$_3$, for example the photon correlation spectroscopy with visible laser beam (Yan et al., 2008), Namikawa's experiment employs pulsed soft x-ray laser as the light source. For this sake, the size of photo-created ferroelectric cluster is reduced to a few nanometers, and the cluster relaxation time is at a scale of picosecond. This measurement, thus, uncovers new critical properties of the ultrafast relaxation dynamics of polarization clusters.

2. Theoretical model and methods

In this and next sections, we examine the newly reported novel behaviours of ferroelectric cluster observed by Namikawa from a theoretical point of view, aiming to provide a basis for understanding the critical nature of BaTiO$_3$. Theoretically, the dynamics of a system can be adequately described by the linear response theory, i.e., to express the dynamic quantities in terms of time correlation functions of the corresponding dynamic operators. In general, the path integral quantum Monte Carlo method is computationally feasible to handle the quantum many body problems, for it allows the system to be treated without making any approximation. However, simulation on real time dynamics with Monte Carlo method is still an open problem in computational physics because of the formidable numerical cost of path summation which grows exponentially with the propagation time. The common approach to circumvent this problem is to perform imaginary time path integration followed by analytic continuation, and to compute the real time dynamic quantities using Fourier transformation. In the present study, the real time correlation functions and real time dependence of speckle pattern are investigated following this scheme (Ji et al., 2009).

2.1 Model Hamiltonian

Theoretical interpretations for structural phase transition and domain wall dynamics have be well established in the framework of Krumhansl-Schrieffer model (also known as $q^4$ model) (Krumhansl & Schrieffer, 1975; Aubry, 1975; Schneider & Stoll, 1978; Savkin et al., 2002). In this model, the particles are subject to anharmonic on-site potentials and harmonic inter-site couplings. The on-site potential is represented as a polynomial form of the order parameter such as polarization, displacement, or elasticity, which displays a substantial change around $T_c$. Since the $q^4$ model is only limited to second-order transitions, in the present work we invoke a modified Krumhansl-Schrieffer model (also called $q^6$ model) (Morris & Gooding, 1990; Khare & Saxena, 2008) to study the first-order ferroelectric phase
transition of BaTiO$_3$. In this scenario, the Hamiltonian of BaTiO$_3$ crystal ($\Xi H_f$) is written as (here we let $\hbar=1$),

$$H_f = -\frac{\omega_0}{2} \sum_l \frac{\partial^2}{\partial^2 Q_l^2} + U_0 + U_I,$$

(1)

$$U_0 = \frac{\omega_0}{2} \sum_l \left( Q_l^2 - c_2 Q_l^4 + \frac{c_4}{3} Q_l^6 \right),$$

(2)

$$U_I = -\frac{\omega_0 d_2}{2} \sum_{l,l'} Q_l Q_{l'},$$

(3)

where, $U_0$ and $U_I$ are the on-site potential and inter-site correlation, respectively. $Q_l$ is the coordinate operator for the electric dipole moment due to a shift of titanium ions against oxygen ions, i.e., the $T_{1u}$ transverse optical phonon mode. $\omega_0$ is the dipole oscillatory frequency, $l$ labels the site, and $\langle l,l' \rangle$ in Eq. (3) enumerates the nearest neighboring pairs.

In order to describe the optical response of BaTiO$_3$ due to x-ray scattering, we design a theoretical model to incorporate the radiation field and a weak interplay between radiation and crystal. The total Hamiltonian reads,

$$H = H_p + H_f + H_{pf},$$

(4)

$$H_p = \sum_k \Omega_k a_k^* a_k + \Omega_k = \epsilon |k|.$$  

(5)

Eq. (5) represents the polarized light field, where $a_k^*$ ($a_k$) is the creation (annihilation) operator of a photon with a wave number $k$ and an energy $\Omega_k$, and $c$ is the light velocity in vacuum. In Namikawa’s experiment, the wave length of x-ray is 160 Å, thus the photon energy is about 80 eV. Denoting the odd parity of $T_{1u}$ mode, the photon-phonon scattering is of a bi-linear Raman type,

$$H_{pf} = \frac{V}{N} \sum_{q \neq k} \sum_{a_k} a_k^* a_k \frac{\Omega_k Q_k}{2} \frac{\Omega_q Q_q}{2} \frac{Q_q}{\epsilon - \frac{q}{2} - \frac{k}{2}},$$

(6)

where $V$ is the photon-phonon coupling strength, $Q_q (\Xi N^{1/2} \sum e^{i\theta(Q)})$ the Fourier component of $Q$ with a wave number $q$. Without losing generality, here we use a simple cubic lattice, and the total number of lattice site is $N$.

### 2.2 Optical response to pump and probe photons

Since there are two photons involved in the scattering, the photon-phonon scattering probability can be written as,

$$P(t) = \sum_{\Delta t} \left\{ \left< a_{k_+}(0) a_{k_-}^{\dagger} (\Delta) a_{k_+} (\Delta + t) a_{k_-}^{\dagger} (\Delta + t) a_{k_+} (\Delta + t) a_{k_-} (\Delta) a_{k_+}^{\dagger} (0) \right> \right\},$$

(7)

where

$$\left< \cdots \right> = \text{Tr}(e^{-\beta H} \cdots)/\text{Tr}(e^{-\beta H}).$$

(8)
means the expectation, \( \beta (\equiv 1/k_BT) \) is the inverse temperature, and the time dependent operators are defined in the Heisenberg representation,

\[
O(t) = e^{i\tilde{H}t}O e^{-i\tilde{H}t},
\]

Here, \( t \) denotes the time difference between two incident laser pulses as manifested in Fig. 3, and \( k_0 \) the wave number of incoming photon. After a small time interval \( \Delta \), the photon is scattered out of the crystal. \( k_1 \) and \( k'_0 \) are the wave numbers of the first and second outgoing photons, respectively.

Fig. 3. Pulse sequence in an x-ray laser speckle experiment. The pump and probe pulses of \( k_0 \) creates and detects ferroelectric clusters in the sample of paraelectric BaTiO\(_3\), respectively, and generate new x-ray fields in the direction \( k_1 \) and \( k'_0 \) after a short time interval \( \Delta \).

Treating \( H_{pf} \) as a perturbation, we separate Hamiltonian of Eq. (4) as,

\[
H = H_0 + H_{pf},
\]

where

\[
H_0 = H_p + H_f,
\]

is treated as the unperturbed Hamiltonian. By expanding the time evolution operator in Eq. (9) with respect to \( H_{pf} \),

\[
e^{-i\tilde{H}t} \rightarrow e^{-i\tilde{H}t}\left[1 - i \int_0^t dt_1 \tilde{H}_{pf}(t_1) + \cdots \right],
\]

we find that the lowest order terms which directly depend on \( t \) are of fourth order,

\[
P(t) \rightarrow \int_0^t dt_1 \int_0^t dt_2 \int_0^t dt_3 \int_0^t dt_4 \sum_{k_1, k_0} \left\langle \hat{a}_{k_0} \hat{H}_{pf} (t_1) e^{i\Delta t_1} \hat{a}_{k_0}^\dagger e^{i(t_1 + \Delta)H_\xi} \hat{a}_{k_0} \hat{H}_{pf} (t_2) e^{i\Delta t_2} \hat{a}_{k_0}^\dagger \right
\]

\[
\times \hat{a}_{k_1} e^{-i\Delta t} \hat{H}_{pf} (t_3) \hat{a}_{k_1}^\dagger e^{-i(t_3 + \Delta)H_\xi} \hat{a}_{k_1} e^{-i\Delta t} \hat{H}_{pf} (t_4) \hat{a}_{k_1}^\dagger \right\rangle,
\]

where the operators with carets are defined in the interaction representation,

\[
\hat{O}(t) = e^{i\tilde{H}t}O e^{-i\tilde{H}t}.
\]

Fig. 4 represents a diagram analysis for this phonon-coupled scattering process, where photons (phonons) are depicted by the wavy (dashed) lines, and the upper (lower)
horizontal time lines are corresponding to the bra (ket) vectors (Nasu, 1994). Diagram (a) illustrates the changes of wave number and energy of photons due to the emitted or absorbed phonons. This is noting but the Stokes and anti-Stokes Raman scattering. Whereas, diagrams (b)-(f) are corresponding to the exchange, side band, rapid damping, rapid exchange and mutual damping effects, respectively.

Obviously, diagram (c) brings no time dependence, while diagrams (d), (e) and (f) only contributes a rapid reduction to the time correlation of two laser pulses because of the duality in phonon interchange. In this sense, the time dependence is primarily determined by the diagrams (a) and (b). Thus, the scattering probability turns out to be,

\[
P(t) = \frac{1}{N^4} \sum_{q,q'} \left( \sum_{k,k'} a_k a_{k+q} e^{-i(q-k)t} a_{k+q} a_{k'} e^{-i(q-k)t} \right) \left( \sum_{k,k'} a_k a_{k+q} e^{i(q-k)t} a_{k+q} a_{k'} e^{i(q-k)t} \right)
\]

\[
\times \left( \sum_{k,k'} a_k a_{k+q} e^{-i(q-k)t} a_{k+q} a_{k'} e^{-i(q-k)t} \right) \left( \sum_{k,k'} a_k a_{k+q} e^{i(q-k)t} a_{k+q} a_{k'} e^{i(q-k)t} \right)
\]

\[
\times Q(t) Q(t') Q(t+\beta) Q(t+\beta')
\]

\[
\times e^{i(q-k)t} e^{-i(q-k)t} e^{i(q-k)t} e^{-i(q-k)t}
\]

where the photons and phonons are decoupled, and it become evident that the origin of the \(t\)-dependence is nothing but the phonon (dipole) correlation.

Since the photonic part in Eq. (15) is actually time-independent, and in the case of forward x-ray scattering we have \(|k| \approx |k'| \approx |k''|\), the normalized probability can be simplified as,

\[
P(t) = \frac{1}{N^4} \sum_{q,q'} \left| \langle Q^2_q \rangle Q_{q'q'}(t) \right|^2
\]

\[
\times G_q(t)\left( G_{q'q'}(t) \right)
\]

where

\[
G_q(t) = e^{-it} \left( T \hat{Q}_q(t) \hat{Q}_q(0) \right)
\]

is the real time Green's function of phonon, and \(T\) the time ordering operator. In deriving Eq. (16), we have also made use of the fact that the light propagation time in the crystal is rather short. The Fourier component of Green's function,

\[
G_q(\omega) = \int_{-\infty}^{\infty} dt \ G_q(t) \ e^{-i\omega t}
\]

is related to the phonon spectral function \([\Xi Q_q(\omega)]\) through (Doniach & Sondheimer, 1998),

\[
G_q(\omega) = \int_{-\infty}^{\infty} d\omega' \ A_q(\omega') \left( \frac{1}{1 - e^{-\omega t}} - \frac{e^{-\omega t}}{1 - e^{-\omega t}} \right)
\]

The phonon spectral function describes the response of lattice to the external perturbation, yielding profound information about dynamic properties of the crystal under investigation.

www.intechopen.com
Once we get the spectral function, the scattering probability and correlation function can be readily derived.

\[
A(q, \omega) = \int_0^\infty \frac{d\tau}{\pi} \frac{1}{\Delta^2 + (\omega - \omega_0)^2} \exp(-i\omega_0\tau),
\]

where \(\Delta\) is the energy gap between the two states, \(\omega_0\) is the transition frequency, and \(\tau\) is the imaginary time.

Fig. 4. Double-sided Feynman diagrams for scattering process of photon with electric dipole moment (phonon). The photons and phonons are denoted by the wavy and dashed lines, respectively. In each diagram, the upper and lower horizontal time lines represent the bra and ket vectors, respectively.

### 2.3 Dynamics of crystal

A mathematically tractable approach to spectral function \(A(q, \omega)\) is to introduce an imaginary time phonon Green's function, for it can be evaluated more easily than its real time counterpart. In the real space, the imaginary time Green's function is defined as,

\[
G_{\mu\nu}(r) = -2\left\langle T \hat{Q}_\mu(r) \hat{Q}_\nu(0) \right\rangle,
\]

where \(\hat{Q}_\mu(r)\) and \(\hat{Q}_\nu(0)\) are the operators of the phonon at positions \(r\) and at the origin, respectively.
where $\tau(\equiv t)$ is the argument for imaginary time (unless otherwise noted, we use Roman $t$ for real time and Greek $\tau$ for imaginary time). The imaginary time dependence of an operator in the interaction representation is given by

$$\hat{O}(\tau) = e^{i\tau H_0}Oe^{-i\tau H_0}. \quad (21)$$

Under the weak coupling approximation, and by using the Suzuki-Trotter identity, the Green's function can be rewritten into a path integral form (here we assume $\tau > 0$) (Ji et al., 2004),

$$G_{\tau}(r) = \int Dx \ e^{-\beta\Phi_{\tau}(x)} \left[ -2x_{i}(r)x_{i}(0) \right]. \quad (22)$$

where $x_i$ is the eigenvalue of $Q_i$,

$$Q_i |x_i\rangle = x_i |x_i\rangle, \quad (23)$$

$\Phi_{\tau}(x)$ is the path-dependent phonon free energy,

$$e^{-\beta \Phi_{\tau}(x)} = e^{\int dl \Omega_{\tau}[x(l)]}, \quad (24)$$

with

$$\Omega_{\tau} = -\sum_l \left[ \frac{1}{2\omega_0} \left( \frac{\partial x}{\partial l} \right)^2 + \frac{1}{2} \omega_0 x^2 - \frac{1}{2} \omega_0 c_4 x^4 + \frac{1}{6} \omega_0 c_6 x^6 \right] - \frac{1}{2} \omega_0 d^2 \sum_{l,l'} x_l x_{l'}, \quad (25)$$

and $\Omega_{\tau}$ is the total phonon free energy,

$$e^{-\beta \Phi_{\tau}} = \int Dx \ e^{-\beta \Phi_{\tau}(x)}. \quad (26)$$

In the path integral notation, the internal energy of crystal $E_{\tau}(\equiv \langle \langle H_{\tau} \rangle \rangle)$ is represented as

$$\Omega_{\tau} = \int Dx \ e^{-\beta \Phi_{\tau}(x)} \left[ \omega_0 \sum_l x^2 - \frac{3}{2} c_4 x^4 + \frac{2}{3} c_6 x^6 \right] - \omega_0 d^2 \sum_{l,l'} x_l x_{l'}, \quad (27)$$

from which the heat capacity can be derived as

$$C_{\tau} = \left( \frac{\partial E_{\tau}}{\partial T} \right)_{\nu}. \quad (28)$$

The Green's function of momentum space is given by,

$$G_q(\tau) = \frac{1}{N} \sum_{\nu} e^{i(q(l-n))} G_{\nu}(\tau), \quad (29)$$

which is connected with the phonon spectral function $A_q(\omega)$ through (Bonča & Gubernatis, 1996)

www.intechopen.com
Coherence and Ultrashort Pulse Laser Emission

\[
G_q(t) = -\int_0^\infty \frac{\cosh \left(\frac{\beta^2 t - \tau}{2}\right) \omega}{\sinh \left(\frac{1}{2} \beta \omega\right)} A_q(\omega) d\omega .
\]  

(30)

Solving this integral equation is a notoriously ill-posed numerical problem because of the highly singular nature of the kernel. In order to analytically continue the imaginary time data into real frequency information, specialized methods are developed, such as maximum entropy method (Skilling, 1984) and least squares fitting method (Yamazaki et al., 2003). Ji (Ji et al., 2004) develops an iterative fitting approach to derive the electron spectral function, which gives a rapid and stable convergence of the spectrum without using any prior knowledge or artificial parameter. In the present study, however, the phonon spectral function does not yield a specific sum rule like the case of electron, the iterative fitting method cannot be applied directly. For this sake, we have modified this method by a renormalized iteration algorithm (Ji et al., 2009). Details of the standard and renormalized iterative fitting methods can be found in Appendices 6.2 and 6.3, respectively.

3. Numerical results and discussion

3.1 Optical responses

Based on the path integral formalisms, the imaginary time Green’s function can be readily calculated via a standard quantum Monte Carlo simulation (Ji et al., 2004). Our numerical calculation is performed on a 10x10x10 cubic lattice with a periodic boundary condition. The imaginary time is discretized into 10-20 infinitesimal slices. As already noticed for the analytic continuation (Gubernatis et al., 1991), if the imaginary time Green’s function is noisy, the uncertainty involved in the inverse transform might be very large, and the spectral function cannot be determined uniquely. In order to obtain accurate data from quantum Monte Carlo simulation, a hybrid algorithm (Ji et al., 2004) has been implemented in our calculation. This method is elaborated in the Appendix 6.1. Besides, we pick out each Monte Carlo sample after 100-200 steps to reduce the correlation between adjacent configurations. The Monte Carlo data are divided into 5-10 sets, from which the 95% confidence interval is estimated through 10,000 resampled set averages by the percentile bootstrap method. We found that about 1,000,000 Monte Carlo configurations are sufficient to get well converged spectral functions and real time dynamic quantities.

In the numerical calculation, the phonon frequency \(\omega_0\) is assumed to be 20 meV (Zhong et al., 1994), the inter-site coupling constant \(d_2\) is fixed at a value of 0.032, whereas \(c_4\) and \(c_6\) are selected to make the on-site \(U_0\) a symmetric triple-well potential. As shown in Fig. 5, this triple-well structure is featured by five potential extrema located at \(x_a, \pm x_b\) and \(\pm x_c\), where

\[
x_a = 0 ,
\]

(31)

\[
x_b = \frac{c_4 - \sqrt{c_4^2 - c_6}}{c_6} ,
\]

(32)

\[
x_c = \frac{c_4 + \sqrt{c_4^2 - c_6}}{c_6} .
\]

(33)
Fig. 5. On-site potential $U_0$ for the modified Krumhansl-Schrieffer model in the unit of $\omega_0$. The coordinates of potential extrema are denoted by $x_a$, $x_b$, and $x_c$. $\delta$ and $\xi$ are two parameters adopted to characterize this potential.

Fig. 6. Phonon spectral function along the line $\Gamma X M R$ of Brillouin zone in the paraelectric phase at various temperatures: (a) $1.001T_c$, (b) $1.012T_c$, (c) $1.059T_c$, and (d) $1.176T_c$, where $T_c=386$ K. The inset of panel (a) shows the Brillouin zone with high symmetry lines. The inset of panel (b) represents the spectrum at $\Gamma$ point when $T=1.012T_c$. 

www.intechopen.com
In Figs. 6 and 7, we show the optical responses of crystal, where $c_4 = 2.0132 \times 10^{-2}$ and $c_6 = 3.2595 \times 10^{-4}$ are used. Fig. 6 presents the phonon spectral functions in the paraelectric phase at different temperatures: (a) $T = 1.001 T_c$, (b) $T = 1.012 T_c$, (c) $T = 1.059 T_c$, and (d) $T = 1.176 T_c$, where $T_c = 386$ K. In each panel, the spectra are arranged with wave vectors along the ΓXMR direction of Brillouin zone [see in the inset of panel (a)], and $\omega$ refers to energy. In the inset of panel (b), the spectrum at Γ point for $T = 1.012 T_c$ is plotted. Since the spectra are symmetric with respect to the origin $\omega = 0$, here we only show the positive part of them. In Fig. 6, when the temperature decreases towards $T_c$, as already well-known for the displacive type phase transition, the energy of phonon peak is gradually softened. In addition, a so-called central peak, corresponding to the low energy excitation of ferroelectric cluster, appears at the Γ point. The collective excitation represented by this sharp resonant peak is nothing but the photo-created ferroelectric cluster. On decreasing temperature, spontaneous polarization is developed locally as a dipole fluctuation in the paraelectric phase. This fluctuation can stabilize the photo-created ferroelectric cluster, leading to a dramatically enhanced peak intensity near $T_c$.

The appearance of sharp peak at Γ point nearby $T_c$ signifies a long life-time of the photo-created ferroelectric clusters after irradiation. Thus, near $T_c$, they are more likely to be probed by subsequent laser pulse, resulting in a high intensity of speckle pattern. Keeping this in mind, we move on to the results of scattering probability. In Fig. 7, we show the variation of normalized probability $P(t)/P(0)$ as a function of $t$ (time interval between the pump and probe photons). Temperatures for these curves correspond to those in the panels (a)-(d) of Fig. 6, respectively. In this figure, $P(t)/P(0)$ declines exponentially, showing that the speckle correlation decreases with $t$ increases as a result of the photorelaxation of ferroelectric cluster. When $t$ is long enough, the crystal returns to the equilibrium paraelectric state. In addition, as shown in the figure, the relaxation rate bears a temperature dependence. On approaching $T_c$, the duration for return is prolonged, indicative of a critical slowing down of the relaxation. This is because with the decrease of temperature, the fluctuation of local polarization is enhanced, and a long range correlation between dipole moments is to be established as well, making the relaxation of photo-created clusters slower and slower.
3.2 Critical slowing down of photorelaxation

In order to quantitatively depict the critical slowing down, we introduce a relaxation time $t_r$ to estimate the time scale of relaxation, which is the time for $P(t)$ to be reduced by a factor of $e$ from $P(0)$. In Fig. 7, $P(t)/P(0)/e$ is plotted by a horizontal dashed line. Correspondingly, $t_r$ is the abscissa of the intersection point of relaxation curve and this dashed line. In Fig. 8, the relaxation time for various local potential $U_0$ is presented at $T>T_c$. Here we adopt two legible parameters, $\delta$ and $\xi$, to describe the potential wells and barriers for $U_0$ (see Fig. 5), which are defined by

$$\delta = \frac{U_0(x_\delta) - U_0(x_c)}{\omega_0},$$ (34)

$$\xi = \frac{U_0(x_c)}{\omega_0}.$$ (35)

Provided $\delta$ and $\xi$, $c_4$ and $c_6$ can be derived in terms of Eqs. (32)-(35). The values of $c_4$ and $c_6$ for the calculation of Fig. 8 are listed in Table 1, where we set $\xi=3.061$ and change $\delta$ from 4.239 to 4.639. The leftmost point on each curve denotes the $t_r$ at just above $T_c$, which is a temperature determined from the singular point of $C^\prime \prime$ according to Eq. (28).

Fig. 8. Temperature dependence of relaxation time $t_r$ for various $\delta$ when $T>T_c$, where $\xi$ is fixed at 4.439.

As revealed by the NMR experiment (Zalar et al., 2003), the paraelectric-ferroelectric phase transition of BaTiO$_3$ has both displacive and order-disorder components in its mechanism. Short range dipole fluctuation arises in the paraelectric phase near $T_c$ as a precursor of the order-disorder transition, and condenses into long range ferroelectric ordering below $T_c$. Thus, in the present study, the relaxation of photo-created cluster is also subject to the dynamics of this dipole fluctuation and yields a temperature dependence. As illustrated by the three curves in Fig. 8, if a ferroelectric cluster is created at a temperature close to $T_c$, relaxation of this cluster is slow because of a rather strong dipole fluctuation, which holds the cluster in the metastable ferroelectric state from going back to the paraelectric one. Away...
from \( T_c \), \( t_r \) decreases considerably for the dipole fluctuation is highly suppressed. This behaviour is nothing but the critical slowing down of photorelaxation.

\[
c_4 \quad c_6 \quad \delta \quad \xi \quad T_c (K)
\begin{array}{cccc}
2.0696 \times 10^{-2} & 3.4521 \times 10^{-4} & 4.239 & 3.061 & 340 \\
2.0132 \times 10^{-2} & 3.2593 \times 10^{-4} & 4.439 & 3.061 & 386 \\
1.9596 \times 10^{-2} & 3.0814 \times 10^{-4} & 4.639 & 3.061 & 422 \\
\end{array}
\]

Table 1. Parameters adopted for calculation of Fig. 8.

In Fig. 8, it can also be seen that with the increase of \( \delta \), \( T_c \) moves to the high temperature side so as to overcome a higher potential barrier between the ferroelectric and paraelectric phases. Furthermore, the evolution of \( t_r \) becomes gentle as well, implying a gradual weakening of dipole fluctuation at high temperature region.

In Fig. 8, it can also be seen that with the increase of \( \delta \), \( T_c \) moves to the high temperature side so as to overcome a higher potential barrier between the ferroelectric and paraelectric phases. Furthermore, the evolution of \( t_r \) becomes gentle as well, implying a gradual weakening of dipole fluctuation at high temperature region.

In Fig. 9, we show the temperature dependence of relaxation time \( t_r \) for different \( \xi \) when \( T > T_c \), where \( \delta \) is fixed at 3.061.

In Fig. 9, we show the temperature dependence of relaxation time \( t_r \) for various \( \xi \) when \( T > T_c \), where \( \delta \) is fixed at 4.439. The values of parameters for this calculation are given in Table 2. When \( \xi \) changes from 3.261 to 2.861, as shown in Fig. 9, \( T_c \) gradually increases. This is because with the decrease of \( \xi \), the ferroelectric state at \( x_c \) (refer to Fig. 5) becomes more stable and can survive even larger thermal fluctuation. In a manner analogous to Fig. 6, the evolution of \( t_r \) also displays a sharp decline at low temperature, and becomes more and more smooth as temperature increases.

\[
c_4 \quad c_6 \quad \delta \quad \xi \quad T_c (K)
\begin{array}{cccc}
1.9626 \times 10^{-2} & 3.1070 \times 10^{-4} & 4.439 & 3.261 & 354 \\
2.0132 \times 10^{-2} & 3.2593 \times 10^{-4} & 4.439 & 3.061 & 386 \\
2.0663 \times 10^{-2} & 3.4223 \times 10^{-4} & 4.439 & 2.861 & 404 \\
\end{array}
\]

Probing Ultrafast Dynamics of Polarization Clusters in BaTiO$_3$ by Pulsed Soft X-Ray Laser Speckle Technique

Fig. 10. Temperature dependence of relaxation time $t_r$ for various barrier height $\delta+\xi$ when $T>T_c$, where $\delta\xi=1.5$ is assumed.

In Fig. 10, we plot the temperature dependence of $t_r$ for different barrier heights, i.e., $\delta+\xi$ varies from 7.0 to 8.0, while the ratio of $\delta/\xi$ is fixed at 1.5. Parameters for this calculation are provided in Table 3. As already discussed with Figs. 8 and 9, a larger $\delta$ tends to increases $T_c$ but a higher $\xi$ applies an opposite effect on $T_c$. Combining these two effects, in Fig. 10, one finds that $T_c$ increases if both $\delta$ and $\xi$ are enhanced, indicating that in this case, the change of $\delta$ plays a more significant role than that of $\xi$. Meanwhile, in contrast to Figs. 8 and 9, all the three curves in Fig. 10 present smooth crossovers on decreasing temperature towards $T_c$, signifying that the dipole fluctuation can be promoted by lowering $\xi$ even the temperature is decreased.

Table 3. Parameters adopted for calculation of Fig. 10.

In Namikawa’s experiment, the wavelength of soft x-ray laser is 160 Å, hence the photo-created polarization cluster is of nano scale. However, it should be noted that relaxation process of such a nano-sized cluster is actually beyond our present quantum Monte Carlo simulations because of the size limitation of our model. For small-scale dipole fluctuations, the relaxation becomes relatively fast. This is the primary reason why the experimentally measured relaxation time can reach about 30 picoseconds, being several times longer than our calculated results. In spite of the difference, our calculation has well clarified the critical dynamics of BaTiO$_3$ and the origin of speckle variation.

4. Conclusion

We carry out a theoretical investigation to clarify the dynamic property of photo-created ferroelectric cluster observed in the paraelectric BaTiO$_3$ as a real time correlation of speckle
pattern between two soft x-ray laser pulses. The density matrix is calculated by a perturbative expansion up to the fourth order terms, so as to characterize the time dependence of scattering probability. The cluster-associated phonon softening as well as central peak effects are well reproduced in the phonon spectral function via a quantum Monte Carlo simulation. We show that the time dependence of speckle pattern is determined by the relaxation dynamics of photo-created ferroelectric cluster, which is manifested as a central peak in the phonon spectral function. The photorelaxation of ferroelectric cluster is featured by a critical slowing down on decreasing the temperature. Near the $T_c$, cluster excitation is stabilized by the strong dipole fluctuation, correspondingly the relaxation becomes slow. While, at higher temperature, dipole fluctuation is suppressed, ending up with a quicker relaxation of cluster. Our simulation also illustrates that the critical slowing down and dipole fluctuation are subject to the chemical environment of crystal.

6. Appendices

6.1 Hybrid Monte Carlo method

The Metropolis algorithm is a widely used sampling rule for the Monte Carlo simulation. It randomly generates a new configuration from the previous one and accept it with the probability $\min[1, \exp(-\Delta E)]$, where $\Delta E$ is the energy difference between the initial and final configurations. In the present case of interacting many-body system, however, the Metropolis algorithm works only slowly, because we have to sum up a great number of paths and the phonon coordinate covers a large spatial extent. Nevertheless, we find the so-called hybrid Monte Carlo algorithm (Duane et al., 1987) is very efficient. By introducing an extra degree of freedom, it adequately combines the heat bath scheme with the Metropolis algorithm so as to achieve a rapid and ergodic evolution through the configuration space.

In order to incorporate this hybrid Monte Carlo algorithm to our path-integral theory, we first discretize the imaginary time $\tau$, dividing $\beta$ into $L$ segments with interval $\Delta$. Then, from Eqs. (24) and (26) we write the partition function ($\equiv Z$) as,

$$
Z = e^{-\beta \Phi_0} = \int Dx \exp \left\{ -\int_0^\beta d\tau \Omega_f(x(t)) \right\},
$$

$$
= \int Dx \exp \left\{ -\Delta \sum_{i=1}^L \Omega_f(x_i) \right\}.
$$

(36)

Then we introduce a “pseudo time” $\dot{t}$, and velocity field $\dot{x}$, which is the derivative of $x$ with respect to this pseudo time. Then, we define a new pseudo crystal with its partition function ($\equiv Z_p$) given by

$$
Z_p = Z \int \mathbb{D}\dot{x} \exp \left\{ -\sum_{i,j} A_{ij} \dot{x}_i \dot{x}_j \right\}.
$$
where \( i \) and \( l \) refer to imaginary time \( \tau \) and real lattice site, respectively, and

\[
\sum_{i,l} \left( \frac{x_{i,l}^2}{2} + \frac{1}{2\omega_0\Delta} (x_{i,l} - x_{i-1,l})^2 \right) + \frac{\Delta}{2} \omega_0 \dot{x}_{i,l}^2 - \frac{\Delta}{2} \omega_0 \ddot{x}_{i,l} \dot{x}_{i,l}^2 + \frac{\Delta}{6} \omega_0 \dddot{x}_{i,l} \dot{x}_{i,l}^6.
\]

Because the Gaussian noise in Eq. (37) can be integrated out of the partition function \( Z_P \), the introduction of the auxiliary degree of freedom actually gives no effect on the thermal average involving \( x \), and the new configurations for Monte Carlo sampling thus can be determined by the Hamilton’s principle

\[
\delta L_P(x,\dot{x},t)dt = 0,
\]

where \( t_1 \) and \( t_2 \) are the initial and final pseudo times, respectively, and \( L_P \) is the Lagrangian of the pseudo crystal defined as

\[
L_P(x,\dot{x},t) = \sum_{i,l} x_{i,l}^2 - H_P(x,\dot{x},t).
\]

Expanding Eq. (39) with respect to \( \delta x \) and \( \delta \dot{x} \), we obtain the ordinary Hamilton’s equation

\[
\ddot{x}_{i,l} = -\frac{\partial H_P(x,\dot{x},t)}{\partial x_{i,l}}.
\]

To generate the new configurations, the following scheme of molecular dynamics is cycled. For a given set of \( x \), we first update \( \dot{x} \) field using a heat bath, i.e., set each \( \dot{x}_{i,l} \) to be a random number of Maxwell-Boltzmann distribution. Next we propagate \( x \) and \( \dot{x} \) forward along pseudo time \( t \) according to the Hamilton’s equation (41). To this end, we divide the time interval into \( N_t \) molecular-dynamics steps, which is 20 ~ 40 in this work. Compute \( \dot{x} \) at \( \frac{1}{\delta t}, \frac{1}{2\delta t}, \ldots, (N_t - \frac{1}{2})\delta t \), \( N_t\delta t \) \( \delta t = (t_2 - t_1)/N_t \) and \( x \) at \( \delta t, 2\delta t, 3\delta t, \ldots, N_t\delta t \) by the “leap-frog” algorithm (Allen & Tildesley, 1989). Then this evolved configuration is accepted according to the Metropolis algorithm.

### 6.2 Iterative fitting method

With the Green’s function calculated by the QMC simulation, the phonon spectral function \( A(\omega) \) can be numerically attained by the analytic continuation of Eq. (30). Before we proceed to calculate the phonon spectral function, in this section, we first address how to derive the spectral function of electron. We shall see, the electron-oriented iterative fitting algorithm developed here is the cornerstone for a more general approach towards solving the problem of spectrum reconstruction, like that related with phonon.

In the case of electron, the spectral function \( A(\omega) \) is connected to the electronic Green’s function \( G(\tau) \) by an equation similar to Eq. (30),
In terms of Eq. (42), the numerical calculation starts from the following equation,

$$ G_j = \sum K_j A_j, \quad (43) $$

where $i$ and $j$ denote the discretized imaginary time $\tau$ and frequency $\omega$, respectively, and $K_j = \frac{e^{-i\tau \omega}}{1 + e^{-i\beta \omega}}$ is the integral kernel. In order to perform this analytic continuation efficiently, we have developed an iterative fitting method (Ji et al., 2004), which can reproduce the normalized and positive-definite spectra self-consistently. Our algorithm is based on the sum-rule of electronic spectrum (Mahan, 1990)

$$ \sum_j A_j = 1, \quad (45) $$

which suggests that the spectral function can be rewritten in an iterative form as

$$ A_j^{(N)} = \frac{n_j^{(N)}}{N\Delta \omega}, \quad (46) $$

where $n_j^{(N)}$ is the bin counter for the $j$-th spectral segment $A_j^{(N)}$ and records the times that the $j$-th bin being used during the previous $N$ iterative steps. The sum rule of Eq. (45) is thus fulfilled by

$$ N = \sum_j n_j^{(N)}. \quad (47) $$

The positivity of $A_j^{(N)}$ is also guaranteed because $n_j^{(N)}$ is nonnegative.

To reproduce the spectral function, we start from a flat spectrum, and then repeat the following scheme:

1. First we calculate the Green’s function $G_i^{(N)}$ by the current spectral function $A_j^{(N)}$ as,

$$ G_i^{(N)} = \sum_j K_i A_j^{(N)} \Delta \omega. \quad (48) $$

2. Then measure the distance $\Xi [x^{(N)}]$ between $G_i^{(N)}$ and the true $G_i$ (QMC results) as

$$ \Xi [x^{(N)}] = \sum_i [G_i^{(N)} - G_i]_+, \quad (49) $$

which finally should be minimized by the present iteration.

3. Make a trial spectral function $A_j^{(N+1)}$ of the next step $N+1$, whose $n_j^{(N+1)}$ is different from $n_j^{(N)}$ by only one, and only in a randomly selected bin $j_0$ as

$$ n_j^{(N+1)} = n_j^{(N)} + \delta_{j_0}. \quad (50) $$
By this change, we have new $A_i^{(N+1)}$, $G_i^{(N+1)}$ and $\chi_i^{(N+1)}$ for this trial step.

(4) Calculate the difference $S$ as

$$S = \chi_i^{(N)} - \chi_i^{(N+1)} + \sum_j G_j^{(N+1)} - G_j^{(N)}.$$  

(51)

If $S>0$, we accept the change Eq. (50), and start a new cycle from (1). Otherwise, reject this change Eq. (50) and return to (3).

Here let us explain the meaning of $S$ of Eq. (51). In Eq. (49), $\chi_i^{(N)}$ gives the distance from the true $G$ to the trial $G_i^{(N)}$, in a hyperspace spanned by various $G$'s, $G_i^{(N)}$'s and $G_i^{(N+1)}$'s, as schematically shown in Fig. 11. The equi-distant sphere is also symbolically denoted by $S_1$ in this figure. If $\chi_i^{(N)}>\chi_i^{(N+1)}$, or $G_i^{(N+1)}$ is in this sphere $S_1$, we, of course, have to accept this change Eq. (50) unconditionally, since the distance becomes shorter than before. However, $\chi_i^{(N)}$ may not be a simple function of this change, but will be a nonlinear and complicated function. In some cases, $\chi_i^{(N)}$ will be in a local minimum with respect to the change $\Delta$, and this change cannot make the distance shorter. For this reason, in Eq. (51), we introduce a “relaxation effect” through the third term, which avoids the search for $\chi^{(N)}$ being trapped in such a local minimum. Since the projection of $\Delta$ on the vector $G_i^{(N)}-G$ is just -$S/2\chi_i^{(N)}$, we find that the acceptable region for the trial $G_i^{(N+1)}$ consists of two sections, i.e., i and ii (see in Fig. 11), both of which correspond to $S>0$. In section i, $G_i^{(N+1)}$ is unconditionally accepted, since $\chi_i^{(N+1)}$ truly decreases. While in section ii, the acceptance is conditional, since it does not give a smaller $\chi_i^{(N+1)}$ but only make $G_i^{(N+1)}$ moves toward $G$ along the $G-G_i^{(N)}$ line. By taking this conditional acceptance, the minimization is relaxed, and correspondingly an uphill search for a more global minimum can be continued.

With the algorithm described above, the spectral function can be readily recovered from the Green’s function. A few hundred iterations are sufficient to construct the convergent spectra, but with very rough contours. For a naturally refined line shape, much more iterations are necessary before no appreciable change can be observed any more.

Fig. 11. Schematic interpretation for the recipe of analytic continuation. The hypersphere $S_1$ is centered at $G$ with radius $\chi^{(N)}$, and $S_2$ is centered at $G_i^{(N)}$ with radius $|\Delta|$. The hyperplane $P$ is perpendicular to $G_i^{(N)}-G$ and bisects $S_2$. The surface of $S_2$ is thus composed of three sections: i (unconditional acceptance), ii (conditional acceptance) and iii (rejection).
6.3 Renormalization iterative fitting method

The iterative fitting method relies its convergence on the sum-rule of electronic spectrum, which conserves the total spectral weight through the iteration process. In a same manner, the Green’s function and spectral function can be introduced to describe a bosonic system. It can be shown that in the case of boson, Eq. (42) should be reformulated as

\[
G(t) = \int_{-\infty}^{\infty} \frac{e^{-\tau \omega}}{1 - e^{-\beta \omega}} A(\omega) d\omega ,
\]

(53)

and the sum rule also holds for the bosonic spectrum \( A(\omega) \). Hence we can apply the iterative fitting method to calculate it.

However, for the phonon spectrum, there is not a rule that conserves the total spectral sum like that of electron. This is because the phonon Green’s function is defined in the coordinate representation rather the particle number representation [see Eqs. (17) and (20)]. Such a definition leads to general properties of phonon spectrum as manifested by

\[
\omega A(\omega) \geq 0 ,
\]

(54)

\[
A(-\omega) = -A(\omega) .
\]

(55)

Obviously, the phonon spectrum is anti-symmetric and the total sum of spectral weight should be zero,

\[
\int_{-\infty}^{\infty} A(\omega) d\omega = 0 .
\]

(56)

Therefore, the standard iterative fitting method does not work for phonon.

In order to get the phonon spectral function \( A(\omega) \), we need to confine our calculation in the region \( 0 < \omega < \infty \), and introduce a renormalized spectral function \( \tilde{A}(\omega) \) as

\[
\tilde{A}(\omega) = \frac{1}{G(\beta)} \coth \left( \frac{1}{2} \beta \omega \right) A(\omega) .
\]

(57)

Because of the anti-symmetry of \( A(\omega) \), the integral in Eq. (53) can be rewritten as

\[
G(t) = \int_{0}^{\infty} \frac{1}{\cosh \left( \frac{1}{2} \beta \omega \right)} \cosh \left[ \left( \frac{1}{2} \beta - \frac{1}{2} \right) \omega \right] G(\beta) \tilde{A}(\omega) d\omega .
\]

(58)

It is easy to see the renormalized spectral function is positive if \( \omega > 0 \), and satisfies a sum rule,

\[
\int_{0}^{\infty} \tilde{A}(\omega) d\omega = 1 ,
\]

(59)

which allow us to solve the integral equation of Eq. (58) by the iterative fitting approach in the region \( 0 < \omega < \infty \). Once \( \tilde{A}(\omega) \) is reproduced, the phonon spectral function \( A(\omega) \) can be obtained from Eq. (57).
7. References
