Particle Scale Simulation of Heat Transfer in Fluid Bed Reactors

Zongyan Zhou, Qinfu Hou and Aibing Yu

Laboratory for Simulation and Modelling of Particulate Systems
School of Materials Science and Engineering,
The University of New South Wales, Sydney, NSW 2052, Australia

1. Introduction

Fluid bed reactors have been extensively used in chemical processes due to their high heat transfer efficiency (Kunii & Levenspiel, 1991). Typical examples are ironmaking blast furnace which involves complicated multiphase flow, heat transfer and chemical reactions in a packed bed (Omori, 1987; Dong et al., 2007), and fluidized bed combustors whose performance heavily depends on the hydrodynamics and thermal-chemical behavior of particles in interaction with gas (Avedesia & Davidson, 1973; Oka, 2004). To achieve optimal design and control of such a fluid bed reactor, it is important to understand the flow and heat transfer characteristics. The thermal behaviour of packed beds with a stagnant or dynamic fluid has been extensively investigated experimentally and theoretically in the past decades. Many empirical correlations have been formulated to determine the heat transfer coefficient (HTC), as respectively reviewed by various investigators (Botterill, 1975; Wakao & Kaguei, 1982; Kunii & Levenspiel, 1991; Molerus & Wirth, 1997). Those studies and resulting formulations are mainly macroscopic, focused on the overall heat transfer behaviour. They are very useful to the estimation of the thermal behaviour of process designs.

Physical experiments usually experience difficulty in quantifying the heat transfer mechanisms at a particle level identified many years ago (for example, Yagi & Kunii, 1957). To overcome this difficulty, in recent years, heat transfer behaviour in a fluidized bed at a microscopic, particle scale has been examined experimentally (Prins et al., 1985; Baskakov et al., 1987; Agarwal, 1991; Parmar & Hayhurst, 2002; Collier et al., 2004; Scott et al., 2004). In such a study, the transient temperature of a hot sphere immersed in the bed is measured using an attached thermocouple, and then its HTC can be determined. Such particle scale studies are useful but have limitations in exploring the fundamentals. For example, the heat transfer to a particle should be described by at least three mechanisms, e.g. convection from fluid, conduction from particles or wall, and radiation. However, the contribution of each of these mechanisms is difficult to quantify. Moreover, the heat transfer of a particle will be strongly affected by the local gas-solid flow structure, and hence varies spatially and temporally. The information derived for a single particle may not be reliable because of the difficulty in quantifying such local structures in a particle bed.
Alternatively, mathematical modeling has been increasingly accepted as an effective method to study the heat transfer phenomena in a particle-fluid system. Generally speaking, the existing approaches to modeling particle flow and thermal behavior can be classified into two categories: the continuum approach at a macroscopic level, and the discrete approach at a microscopic/particle level. In the continuum approach, the macroscopic behavior is described by balance equations, e.g., mass, momentum and energy, closed with constitutive relations together with initial and boundary conditions (see, for example, Anderson & Jackson, 1967; Ishii, 1975; Gidaspow, 1994; Enwald et al., 1996). The so called two-fluid model (TFM) is widely used in this approach. In such a model, both fluid and solid phases are treated as interpenetrating continuum media in a computational cell which is much larger than individual particles but still small compared with the size of process equipment (Anderson & Jackson, 1967). However, its effective use heavily depends on the constitutive or closure relations for the solid phase and the momentum exchange between phases which are often difficult to obtain within its framework.

The discrete approach is based on the analysis of the motion of individual particles, typically by means of the discrete particle simulation (DPS). The method considers a finite number of discrete particles interacting by means of contact and non-contact forces. When coupling with fluid flow, a coupled DPS-CFD (computational fluid dynamics) approach is often used. In this approach, the motion of discrete particles is obtained by solving Newton’s second law of motion, and the flow of continuum fluid by solving the Navier-Stokes equations based on the concept of local average as used in CFD, with the coupling of CFD and DPS through particle-fluid interaction forces (Tsuji et al., 1992; Xu & Yu, 1997; 1998; Zhou et al., 2010b). The main advantage of DPS-CFD is that it can generate detailed particle-scale information, such as the trajectories of and forces acting on individual particles, which is key to elucidating the mechanisms governing the complicated flow behavior. With the rapid development of computer technology, the approach has been increasingly used by various investigators to study various particle-fluid flow systems as, for example, reviewed by Zhu et al. (2007; 2008).

Discrete approach has been extended to study heat transfer. In fact, mechanistic approach based on the packet model originally proposed by Mickley and Fairbanks (1955) is a typical one to study the heat transfer between bubbling beds and immersed objects. However, the problem associated with such early approaches is the lack of reliable estimation of parameters (Chen, 2003; Chen et al., 2005). This difficulty can be overcome by the newly developed discrete approach. With the DPS-CFD approach, information such as particle-particle or particle-wall contact, local voidage and local gas-solid flow structure can be produced. Such information is essential in determining the heat transfer behaviour of individual particles. The approach has been attempted by some investigators to study coal combustion (Rong & Horio, 1999; Peters, 2002; Zhou et al., 2003; Zhou et al., 2004), air drying (Li & Mason, 2000; Li & Mason, 2002), olefin polymerization (Kaneko et al., 1999), and inserts in a fluidized bed (Di Maio et al., 2009; Zhao et al., 2009). But in those studies, the heat transfer mode by particle-particle conduction is only partially considered. The analysis of heat transfer mechanisms has not been performed seriously.

More recently, Zhou et al. (2009; 2010a) proposed a comprehensive model taking into account most of the known heat transfer mechanisms. The approach considers the different heat transfer mechanisms in detail, for example, particle-fluid convection, particle-particle...
conduction, and particle radiation. The extended DPS-CFD model offers a useful numerical technique to elucidate the fundamentals governing the heat transfer in packed/fluidized beds at a particle scale. This chapter aims to introduce this approach, and demonstrates its applications through some case studies.

2. Model description

2.1 Governing equations for solid particles

Various methods have been developed for DPS simulation, as reviewed by Zhu et al. (2007). The DPS model used here is based on the soft sphere model, i.e. discrete element method (DEM), originally proposed by Cundall and Strack (1979). Generally, a particle in a particle-fluid flow system can have two types of motion: translational and rotational, which are determined by Newton’s second law of motion. The corresponding governing equations for particle $i$ with radius $R_i$, mass $m_i$ and moment of inertia $I_i$ can be written as:

$$m_i \frac{dv_i}{dt} = f_{f,i} + \sum_{j=1}^{k} (f_{c,ij} + f_{d,ij}) + m_i g$$  \hspace{1cm} (1)$$

$$I_i \frac{d\omega_i}{dt} = \sum_{j=1}^{k} (M_{r,ij} + M_{t,ij})$$  \hspace{1cm} (2)$$

where $v_i$ and $\omega_i$ are respectively the translational and angular velocities of the particle. The forces involved are: particle-fluid interaction force $f_{f,i}$, the gravitational force $m_i g$, and inter-particle forces between particles which include elastic force $f_{c,ij}$ and viscous damping force $f_{d,ij}$. These inter-particle forces can be resolved into the normal and tangential components at a contact point. The torque acting on particle $i$ by particle $j$ includes two components: $M_{t,ij}$ which is generated by tangential force and causes particle $i$ to rotate, and $M_{r,ij}$ commonly known as the rolling friction torque, is generated by asymmetric normal forces and slows down the relative rotation between particles. A particle may undergo multiple interactions, so the individual interaction forces and torques are summed over the $k$ particles interacting with particle $i$.

Equations used to calculate the interaction forces and torques between two spheres have been well-established in the literature (Zhu et al., 2007). In our work, the determination of particle-particle interaction is based on the non-linear models, as listed in Table 1. This approach was also used by other investigators (Langston et al., 1994; 1995; Zhou et al., 1999; Yang et al., 2000). Particle-fluid interaction force $f_{f,i}$ is a sum of fluid drag $f_{d,i}$ and pressure gradient force $f_{\nabla p,i}$. Many correlations are available in the literature to calculate the fluid drag acting on the individual particles, for example, Ergun equation (1952), Wen and Yu (1966), and Di Felice (1994). Particularly, Di Felice correlation (1994) has been widely used in the literature and also used in our work (see, for example, Xu & Yu, 1997; Xu et al., 2000; Feng & Yu, 2004; 2007; Zhou et al., 2009; 2010a; 2010b).

The heat transfer of particle $i$ and its surroundings is considered to be controlled by three mechanisms: particle-fluid convection, particle-particle or particle-wall conduction, and radiation. According to the energy balance, the governing equation for particle $i$ can be generally written as
where \( k_i \) is the number of particles exchanging heat with particle \( i \), \( Q_{ij} \) is the heat exchange rate between particles \( i \) and \( j \) due to conduction, \( Q_{ij}^{C} \) is the heat exchange rate between particle \( i \) and its local surrounding fluid, \( Q_{i,nrad} \) is the heat exchange rate between particle \( i \) and its surrounding environment by radiation, and \( Q_{i,wall} \) is particle-wall heat exchange rate. 

\( c_{p,i} \) is the particle specific heat. Different heat exchange rates shown in Eq. (3), and described below.

\[
\frac{m_i c_{p,i}}{d t} = \sum_{j=1}^{k_i} Q_{ij} + Q_{i,f} + Q_{i,nrad} + Q_{i,wall}
\]

Table 1. Components of forces and torques on particle \( i \)

**Conductive heat transfer**

Convective heat transfer between particles and fluid has been extensively investigated since 1950s, and different equations have been proposed (Botterill, 1975; Wakao & Kagwey, 1982; Kunii & Levenspiel, 1991; Molerus & Wirth, 1997). Often, the convective heat transfer rate between particle \( i \) and fluid is calculated according to \( Q_{i,f} = h_{conv,i} A_i(T_{i,j} - T_{j}) \), where \( A_i \) is the particle surface area, \( T_{i,j} \) is fluid temperature in a computational cell where particle \( i \) is located, and \( h_{conv,i} \) is the convective HTC. \( h_{conv,i} \) is associated with the Nusselt number, which is a function of particle Reynolds number and gas Prandtl number, given by
\[ \text{Nu}_i = h_{i,\text{conv}} d_p i / k_f = 2.0 + a \text{Re}_p^b \text{Pr}^{1/3} \]  

where \( k_f \) and \( d_p \) are the fluid thermal conductivity and particle diameter, respectively. \( \text{Re}_p \) is the local relative Reynolds number for particle \( i \) (Table 1). The gas (air) Prandtl number, \( \text{Pr} \), is a material property. The constant, 2.0, represents the contribution by particle-fluid natural convection. \( a \) and \( b \) are two parameters that need to be evaluated. As suggested by Kunii and Levenspiel (1991), \( b=0.5 \), and \( a \) could range from 0.6 to 1.8, depending on the bed conditions.

For fluid-wall heat transfer, \( \text{Nu}_{D} = h_{f,\text{wall}} D / k_f = 0.023 \text{Re}^{0.8} \text{Pr}^{n} \) is used to determine the heat transfer coefficient \( h_{f,\text{wall}} \), where \( D \) is the hydraulic diameter, and the exponent \( n \) is 0.4 for heating, and 0.3 for cooling (Holman, 1981).

Conductive heat transfer

Conduction between particles involves various mechanisms (Yagi & Kunii, 1957; Cheng et al., 1999), which mainly include (i) particle-fluid-particle conduction heat transfer; and (ii) particle-particle conduction heat transfer, as indicated in Fig. 1. The model details for those two mechanisms are described as follows.

Particle-fluid-particle heat transfer has been examined by various investigators (Delvosalle & Vanderschuren, 1985; Cheng et al., 1999). The model proposed by Cheng et al. (1999) is used here after some modification. According to this model, the heat transfer flux between spheres \( i \) and \( j \) is written as

\[ Q_{i,j} = (T_j - T_i) \int_{r_{ij}}^{r_j} \frac{2\pi \cdot r dr}{\sqrt{R^2 - r^2 - r(R + H)/r_j} \cdot \left[ 1/k_{pi} + 1/k_{pj} \right] + 2[(R + H) - \sqrt{R^2 - r^2}]/k_f} \]
where \( k_{pi} \) and \( k_{pj} \) are the thermal conductivities of particles \( i \) and \( j \), respectively. For the details of parameters of \( H \), \( r_{sf} \) and \( r_{ij} \) see the reference of Zhou et al. (2009). The heat flux between two particles is ignored when the distance of 2H is greater than particle radius \( R \).

Conduction heat transfer always occurs through the contacted area between particles or between particles and wall. Generally, such conduction heat transfer due to elastic deformation includes two mechanisms: conduction due to particle-particle static contact (particularly common in a packed bed) and conduction due to particle-particle collision, which occurs in a moving or fluidized bed. For conduction due to particle-particle static contact, the equation proposed by Batchelor and O’Brien (Batchelor & O’Brien, 1977) and modified by Cheng et al. (1999) is adopted. Thus, the heat flux \( Q_{ij} \) through the contact area between particles \( i \) and \( j \) can be calculated according to the equation below:

\[
Q_{ij} = \frac{4r_{c}(T_{i} - T_{j})}{(1/k_{pi} + 1/k_{pj})}
\]

Particle-particle heat transfer due to collision is normally determined by the model proposed by Sun and Chen (1988). Recently, Zhou et al. (2008) provided a modified equation that can be readily implemented in the DPS-CFD model:

\[
Q_{ij} = c'\left(\frac{r_{c}t_{c}^{3/2}(T_{i} - T_{j})}{(\rho_{pi}c_{pi}k_{pi})^{1/2} + (\rho_{pj}c_{pj}k_{pj})^{1/2}}\right)
\]

where \( r_{c} \) and \( t_{c} \) are particle-particle contact radius and contact duration, respectively. To be consistent with the current model, \( r_{c} \) is obtained from the DEM simulation which is based on the Hertz elastic contact theory (see Table 1). For particle-wall static or collision contact, a wall can be treated as a particle with an infinite diameter and mass, as commonly used in the DEM work. Its properties are assumed to be the same as particles.

It should be noted that the two mechanisms represented by Eqs. (6) and (7) must be distinguished in computation (Zhou et al., 2009). For fixed beds, particle-particle contacts are all static. Thus only static contact heat transfer applies. For fluidized beds, two parameters are set: particle-particle collision time \( t_{c} \) and particle-particle contact duration time \( t_{d} \) which can be obtained from simulation. For two colliding particles, if \( t_{c} \geq t_{d} \), only collisional heat transfer applies. If \( t_{c} < t_{d} \), two particles will keep in touch after collision. In such a case, collision heat transfer applies first during the time of \( t_{c} \), and then static heat transfer during the time of \( (t_{d} - t_{c}) \).

**Radiative heat transfer**

In a fixed or fluidized bed, a particle is surrounded by particles and fluid. In a specified enclosed cell, an environmental temperature is assumed to represent the enclosed surface temperature around such a particle. Thus, the equation used by Zhou et al. (2004) is slightly modified to calculate the heat flux due to radiation using a local environmental temperature to replace the bed temperature, and is written as (Zhou et al., 2009)

\[
Q_{i,rad} = \sigma_{0}\varepsilon A_{i}(T_{\text{local},j}^{4} - T_{i}^{4})
\]
where $\sigma$ is the Stefan-Boltzmann constant, equal to $5.67 \times 10^{-8}$ W/(m$^2$K$^4$), and $\varepsilon_{pi}$ is the sphere emissivity. Gas radiation is not considered due to low gas emissivities. The parameter $T_{\text{local},i}$ is the averaged temperature of particles and fluid by volume fraction in an enclosed spherical domain $\Omega$ given by (Zhou et al., 2009)

$$T_{\text{local},i} = \varepsilon_f T_{f,\Omega} + (1 - \varepsilon_f) \frac{1}{k_{\Omega}} \sum_{j=1}^{k_{\Omega}} T_j \ (j \neq i)$$

(9)

where $T_{f,\Omega}$ and $k_{\Omega}$ are respectively the fluid temperature and the number of particles located in the domain $\Omega$ with its radius of $1.5d_p$. To be fully enclosed, a larger radius can be used.

### 2.2 Governing equations for fluid phase

The continuum fluid field is calculated from the continuity and Navier-Stokes equations based on the local mean variables over a computational cell, which can be written as (Xu et al., 2000)

$$\frac{\partial \varepsilon_f}{\partial t} + \nabla \cdot (\varepsilon_f \mathbf{u}) = 0$$

(10)

$$\frac{\partial (\rho_f \varepsilon_f \mathbf{u})}{\partial t} + \nabla \cdot (\rho_f \varepsilon_f \mathbf{u} \mathbf{u}) = -\nabla p + \nabla \cdot \mathbf{F}_p + \varepsilon_f \mathbf{r} + \rho_f \varepsilon_f \mathbf{g}$$

(11)

And by definition, the corresponding equation for heat transfer can be written as

$$\frac{\partial (\rho_f \varepsilon_f \mathbf{e}_p T)}{\partial t} + \nabla \cdot (\rho_f \varepsilon_f \mathbf{e}_p \mathbf{u} T) = \nabla \cdot (\varepsilon_f \Gamma \nabla T) + \sum_{i=1}^{k_f} Q_{f,i} + Q_{f,\text{wall}}$$

(12)

where $\mathbf{u}$, $\rho_f$, $p$ and $\mathbf{F}_p = \left( \sum_{i=1}^{k_f} \mathbf{f}_{p,i} \right) / \Delta V$ are the fluid velocity, density, pressure and volumetric fluid-particle interaction force, respectively, and $k_f$ is the number of particles in a computational cell of volume $\Delta V$. $\Gamma$ is the fluid thermal diffusivity, defined by $\mu/\sigma_f$, and $\sigma_f$ the turbulence Prandtl number. $Q_{f,i}$ is the heat exchange rate between fluid and particle $i$ which locates in a computational cell, and $Q_{f,\text{wall}}$ is the fluid-wall heat exchange rate. $\mathbf{r} = \varepsilon_f \mathbf{r}$ is the fluid viscous stress tensor and porosity, respectively. $V_{p,i}$ is the volume of particle $i$ (or part of the volume if the particle is not fully in the cell), $\mu$, the fluid effective viscosity determined by the standard k-$\varepsilon$ turbulent model (Lauder & Spalding, 1974).

### 2.3 Solutions and coupling schemes

The methods for numerical solution of DPS and CFD have been well established in the literature. For the DPS model, an explicit time integration method is used to solve the translational and rotational motions of discrete particles (Cundall & Strack, 1979). For the CFD model, the conventional SIMPLE method is used to solve the governing equations for the fluid phase (Patankar, 1980). The modeling of the solid flow by DPS is at the individual particle level, whilst the fluid flow by CFD is at the computational cell level. The coupling methodology of the two models at different length scales has been well documented (Xu & Yu, 1997; Feng & Yu, 2004; Zhu et al., 2007; Zhou et al., 2010b). The present model simply
extends that approach to include heat transfer, and more details can be seen in the reference of Zhou et al. (2009).

Fig. 2. Snapshots showing the heating process of fluidized bed by hot gas (1.2 m/s, 100°C) uniformly introduced from the bottom (Zhou et al., 2009).

3. Model application

3.1 Heat transfer in gas fluidization with non-cohesive particles

Gas fluidization is an operation by which solid particles are transformed into a fluid-like state through suspension in a gas (Kunii & Levenspiel, 1991). By varying gas velocity, different flow patterns can be generated from a fixed bed (U<U_{mf}) to a fluidized bed. The solid flow patterns in a fluidized bed are transient and vary with time, as shown in Fig. 2, which also illustrates the variation of particle temperature. Particles located at the bottom are heated first, and flow upward dragged by gas. Particles with low temperatures descend and fill the space left by those hot particles. Due to the strong mixing and high gas-particle heat transfer rate, the whole bed is heated quickly, and reaches the gas inlet temperature at around 70 s. The general features observed are qualitatively in good agreement with those reported in the literature, confirming the predictability of the proposed DPS-CFD model in dealing with the gas-solid flow and heat transfer in gas fluidization.

The cooling of copper spheres at different initial locations in a gas fluidized bed was examined by the model (Zhou et al., 2009). In physical experiments, the temperature of hot spheres is measured using thermocouples connected to the spheres (Collier et al., 2004; Scott...
et al., 2004). But the cooling process of such hot spheres can be easily traced and recorded in the DPS-CFD simulations, as shown in Fig. 3a. The predicted temperature is comparable with the measured one. The cooling curves of 9 hot spheres are slightly different due to their different local fluid flow and particle structures. In the fixed bed, such a difference is mainly contributed to the difference in the local structures surrounding the hot sphere. But in the fluidized bed, it is mainly contributed to the transient local structure and particle-particle contacts or collisions. Those factors determine the variation of the time-averaged HTCs of hot spheres in a fluidized bed.

![Fig. 3. (a) Temperature evolution of 9 hot spheres when gas superficial velocity is 0.42 m/s; and (b) time-averaged heat transfer coefficients of the 9 hot spheres as a function of gas superficial velocity (Zhou et al., 2009).](image)

The comparison of the HTC-U relationship between the simulated and the measured was made (Zhou et al., 2009). In physical experiments, Collier et al. (2004) and Scott et al. (2004) used different materials to examine the HTCs of hot spheres, and found that there is a general tendency for the HTC of hot sphere increasing first with gas superficial velocity in the fixed bed \(U<U_{mf}\), and then remaining constant, independent on the gas superficial velocities for fluidized beds \(U>U_{mf}\). The DPS-CFD simulation results also exhibit such a feature (Fig. 3b). For packed beds, the time-averaged HTC increases with gas superficial velocity, and reaches its maximum at around \(U=U_{mf}\). After the bed is fluidized, the HTC is almost constant in a large range.

The HTC-U relationship is affected significantly by the thermal conductivity of bed particles (Zhou et al., 2009). The higher the \(k_p\), the higher the HTC of hot spheres (Fig. 4). For example, when \(k_p=30\) W/(m·K), the predicted HTC in the fixed bed \(U/U_{mf}<1\) is so high that the trend of HTC-U relationship shown in Fig. 3b is totally changed. The HTC decreases with \(U\) in the fixed bed, then may reach a constant HTC in the fluidized bed. But when thermal conductivity of particles is low, the HTC always increases with \(U\), independent of bed state (Fig. 4a). Fig. 4b further explains the variation trend of HTC with \(U\). Generally, the convective HTC increases with \(U\); but conductive HTC decreases with \(U\). For a proper particle thermal conductivity, i.e. 0.84 W/(m·K), the two contributions (convective HTC and conductive HTC) could compensate each other, then the total HTC is nearly constant after
the bed is fluidized. So HTC independence of U is valid under this condition. But if particle thermal conductivity is too low or too high, the relationship of HTC and U can be different, as illustrated in Fig. 4a.

Fig. 4. Time-averaged heat transfer coefficients of one hot sphere: (a) total HTC calculated by different equations; and (b) convective HTC (solid line) and conductive HTC (dashed line) for different thermal conductivities (Zhou et al., 2009).

The proposed DPS-CFD model can be used to analyze the sub-mechanisms shown in Fig. 1a for conduction. The relative contributions by these heat transfer paths were quantified (Zhou et al., 2009). For example, when $k_p=0.08$ W/(m·K), particle-fluid-particle conduction always contributes more than particle-particle contact, but both vary with gas superficial velocity (Fig. 5a). For particle-fluid-particle conduction, particle-fluid-particle heat transfer with two contacting particles is far more important than that with two non-contacting particles.

Fig. 5. Contributions to conduction heat transfer by different heat transfer mechanisms when (a) $k_p=0.08$ W/(m·K); and (b) $k_p=30$ W/(m·K) (Zhou et al., 2009).
particles in the fixed bed. Zhou et al. (2009) explained that it is because the hot sphere contacts about 6 particles when \(U<U_{mf}\). But such a feature changes in the fluidized bed (\(U>U_{mf}\)), where particle-fluid-particle conduction between non-contacting particles is relatively more important. This is because most of particle-particle contacts with an overlap are gradually destroyed with increasing gas superficial velocity, which significantly reduces the contribution by particle-fluid-particle between two contacting particles. However, particle-particle conduction through the contacting area becomes more important with an increase of particle thermal conductivity. The percentage of its contribution is up to 42\% in the fixed bed when \(k_p=30\text{ W/(m}\cdot\text{K})\), then reduces to around 15\% in the fluidized bed (Fig. 5b). Correspondingly, the contribution percentage by particle-fluid-particle heat transfer is lower, but the trend of variation with \(U\) is similar to that for \(k_p=0.08\text{ W/(m}\cdot\text{K})\).

![Fig. 6. Bed-averaged convective, conductive and radiative heat transfer coefficients as a function of gas superficial velocity (Zhou et al., 2009).](image)

It should be noted that a fluid bed has many particles. A limited number of hot spheres cannot fully represent the averaged thermal behaviour of all particles in a bed. Thus, Zhou et al. (2009) further examined the HTCs of all the particles, and found that the features are similar to those observed for hot spheres (Fig. 6). The similarity illustrates that the hot sphere approach can, at least partially, represent the general features of particle thermal behaviour in a particle-fluid bed. Overall, the particles in a uniformly fluidized bed behave similarly. But a particle may behave differently from another at a given time. Zhou et al. (2009) examined the probability density distributions of time-averaged HTCs due to particle-fluid convection and particle conduction, respectively (Fig. 7). The convective HTC in the packed bed varies in a small range due to the stable particle structure. Then the distribution curve moves to the right as \(U\) increases, indicating the increase of convective HTC. The distribution curve also becomes wider. It is explained that, in a fluidized bed, clusters and bubbles can be formed, and the local flow structures surrounding particles vary in a large range. The density distribution of time-averaged HTCs by conduction shows that it has a wider distribution in a fixed bed (curves 1, 2 and 3) (Fig. 7b), indicating different local packing structures of particles. But curves 1 and 2 are similar. It is explained that, statistically, the two bed packing structures are similar, and do not vary much even if \(U\) is different. When \(U>U_{mf}\) (e.g. \(U=2.0U_{mf}\)), the distribution curve moves to the left, indicating...
the heat transfer due to interparticle conduction is reduced. The bed particles occasionally collide and contact each other. Statistically, the number of collisions and contacts are similar in fully fluidized beds, and not affected significantly by gas superficial velocities. Those features are consistent with those observed using the hot sphere approach. It confirms that hot sphere approach can represent the thermal behaviour of all bed particles to some degree.

![Figure 7](https://example.com/figure7.png)

Fig. 7. Probability density distributions of time-averaged heat transfer coefficients of particles at different gas superficial velocities: (a), fluid convection; and (b), particle conduction (Zhou et al., 2009).

The particle thermal behaviour in a fluidized bed is affected by bed temperature. Zhou et al. (2009) carried out a simulation case at high temperature of 1000°C. It illustrated that the radiative HTC reaches 300 W/(m²⋅K), which is significantly larger than that for the case of hot gas with 100°C (around 5 W/(m²⋅K)). The convective and radiative HTCs do not remain constant during the bed heating due to the variation of gas properties with temperature. The conductive heat transfer coefficient is not affected much by the bed temperature. This is because the conductive HTC is quite small in the fluidized bed, and only related to the gas and particle thermal conductivities.

### 3.2 Effective thermal conductivity in a packed bed.

Effective thermal conductivity (ETC) is an important parameter describing the thermal behaviour of packed beds with a stagnant or dynamic fluid, and has been extensively investigated experimentally and theoretically in the past. Various mathematical models, including continuum models and microscopic models, have been proposed to help solve this problem, but they are often limited by the homogeneity assumption in a continuum model (Zehner & Schlunder, 1970; Wakao & Kaguei, 1982) or the simple assumptions in a microscopic model (Kobayashi et al., 1991; Argento & Bouvard, 1996). Cheng et al. (1999; 2003) proposed a structure-based approach, and successfully predicted the ETC and analyzed the heat transfer mechanisms in a packed bed with stagnant fluid. Such efforts have also been made by other investigators (Vargas & McCarthy, 2001; Vargas & McCarthy, 2002a; b; Cheng, 2003; Siu & Lee, 2004; Feng et al., 2008). The proposed structured-based approach has been extended to account for the major heat transfer mechanisms in the calculation of ETC of a packed bed with a stagnant fluid (Cheng, 2003). But it is not so
adaptable or general due to the complexity in the determination of the packing structure and the ignorance of fluid flow in a packed bed. The proposed DPS-CFD model has shown a promising advantage in predicting the ETC under the different conditions (Zhou et al., 2009; 2010a).

Crane and Vachon (1977) summarized the experimental data in the literature, and some of them were further collected by Cheng et al. (1999) to validate their structure-based model (for example, see data from Kannuluk & Martin, 1933; Schumann & Voss, 1934; Waddams, 1944; Wilhelm et al., 1948; Verschoor & Schuit, 1951; Preston, 1957; Yagi & Kunii, 1957; Goring & Churchill, 1961; Krupiczka, 1967; Fountain & West, 1970)). Our work makes use of their collected data. In the structure-based approach (Cheng et al., 1999), it is confirmed that the ETC calculation is independent of the cube size sampled from a packed bed when each cube side is greater than 8 particle diameters. Zhou et al. (2009; 2010a) gave the details on how to determine the bed ETC. The size of the generated packed bed used is $13d_p \times 13d_p \times 16d_p$. 2,500 particles with diameter 2 mm and density 1000 kg/m$^3$ are packed to form a bed by gravity. Then the ETC of the bed is determined by the following method: the temperatures at the bed bottom and top are set constants, $T_b=125\, ^\circ\, C$ and $T_t=25\, ^\circ\, C$, respectively. Then a uniform heat flux, $q$ (W/m$^2$), is generated and passes from the bottom to the top. The side faces are assumed to be adiabatic to produce the un-directional heat flux. Thus, the bed ETC is calculated by $k_e = qH_b/(T_b-T_t)$, where $H_b$ is the height between the two layers with two constant temperatures at the top and the bottom, respectively.

Fig. 8. Effect of Young’s modulus E on the bed ETC (the experimental data represented by circles are from the collection of Cheng et al. (1999)) (Zhou et al., 2010a).

Young’s modulus is an important parameter affecting the particle-particle overlap, hence the particle-particle heat transfer (Zhou et al., 2010a). Fig. 8 shows the predicted ETC for different Young’s modulus varying from 1 MPa to 50 GPa. When $E$ is around 50 GPa, which is in the range of real hard materials like glass beads, the predicted ETC are comparable with experiments. The high ETC for low Young’s modulus is caused by the overestimated particle-particle overlap in the DPS based on the soft-sphere approach. A large overlap significantly increases the heat flux $Q_{ij}$. However, in the DPS, it is computationally very demanding to carry out the simulation using a real Young’s modulus (often at an order of $10^3$–$10^5$ MPa), particularly when involving a large number of particles. This is because a high Young’s modulus requires extremely small time steps to obtain accurate results,
resulting in a high computational cost which may not be tolerated under the current computational capacity. The relationship often used for determining the time step is in the form of $\Delta t \propto \sqrt{m/k}$, where $k$ is the particle stiffness. The higher the stiffness, the smaller the time step. It is therefore very helpful to have a method that can produce accurate results but does not have a high computational cost.

The calculation of heat fluxes for conduction heat transfer mechanisms is related to an important parameter: particle-particle contact radius $r_c$, as seen in Eqs. (6) and (7). Unfortunately, DPS simulation developed on the basis of soft-sphere approach usually overestimates $r_c$ due to the use of low Young's modulus. The overestimation of $r_c$ then significantly affects the calculation of conductive heat fluxes. To reduce such an over-prediction, a correction coefficient $c$ is introduced, and then the particle-particle contact radius used to calculate the heat flux between particles through the contact area is written as

$$r_c' = c \cdot r_c \quad (13)$$

where $r_c'$ is the reduced contact radius by correction coefficient $c$ which varies between 0 and 1, depending on the magnitude of Young’s modulus used in the DPS. The determination of $c$ is based on the Hertzian theory, and can be written as (Zhou et al., 2010a)

$$c = r_{c,0}/r_c = (E_{ij}/E_{ij,0})^{1/5} \quad (14)$$

where $E_{ij}$ is the Young’s modulus used in the DPS simulation and $E_{ij,0}$ the real value of Young’s modulus of the materials considered. Different materials have different Young’s modulus $E_0$. Then the obtained correction coefficients by Eq. (14) are also different, as shown in Fig. 9a. Fig. 9b further shows the applications of the obtained correction coefficients in some cases, where the particle thermal conductivity varied from 1.0 to 80 W/(m⋅K); gas thermal conductivities varied from 0.18 to 0.38 W/(m⋅K); Young’s modulus used in the DPS varies from 1 MPa to 1 GPa, and the real value of Young’s modulus is set to 50 GPa. The results show that the predicted ETCs are well comparable with experiments.

There are many factors influencing the ETC of a packed bed. The main factors are the thermal conductivities of the solid and fluid phases. Other factors include particle size, particle shape, packing method that gives different packing structures, bed temperature, fluid flow and other properties. Zhou et al. (2010a) examined the effects of some parameters on ETC, and revealed the ETC is not sensitive to particle-particle sliding friction coefficient which varies from 0.1 to 0.8. ETC increases with the increase of bed average temperature, which is consistent with the observation in the literature (Wakao & Kaguei, 1982). The predicted ETC at 1475°C can be about 5 times larger than that at 75°C. The effect of particle size on ETC is more complicated. At low thermal conductivity ratios of $k_p/k_f$, the ETC varies little with particle size from 250 μm to 10 mm. But it is not the case for particles with high thermal conductivity ratios, where the ETC increases with particle size. The main reason could be that the particle-particle contact area is relatively large for large particles, and consequently, the increase of $k_p/k_f$ enhances the conductive heat transfer between particles. However, that ETC is affected by particle size offers an explanation as to why the literature
data are so scattered. This is because different sized particles were used in experiments. For particles smaller than 500 μm, the predicted ETC is lower than that measured for high $k_p/k_f$ ratios. This is because large particles were used in the reported experiments. Further studies are required to quantify the effect of particle size on the bed ETC under the complex conditions with moving fluid, size distributions or high bed temperature corresponding to those in experiments (Khraisha, 2002; Fjellerup et al., 2003; Moreira et al., 2005).

Fig. 9. (a) Relationship between correction coefficient and Young’s modulus $E$ used in the DPS, and (b) the predicted ETCs as a function of $k_p/k_f$ ratios for different $E$ using the obtained correction coefficients according to Eq. (14) where $E_0=50$ GPa (Zhou et al., 2010a).

The approach of introduction of correction coefficient has also been applied to gas fluidization to test its applicability. An example of flow patterns has been shown in Fig. 2, which illustrates a heating process of the fluidized bed by hot gas (Zhou et al., 2009). The proposed modified model by an introduction of correction coefficient in this work can still reproduce those general features of solid flow patterns and temperature evolution with time using low Young’s modulus, and the obtained results are comparable to those reported by Zhou et al. (2009) using a high Young’s modulus. Zhou et al. (2010a) compared the obtained average convective and conductive heat transfer coefficients by three treatments: (1) $E=E_0=50$ GPa, and $c=1.0$; (2) $E=10$ MPa, and $c=1.0$; and (3) $E=10$ MPa, and $c=0.182$. Treatment 1 corresponds to the real materials, and its implementation requires a small time step. Treatments 2 and 3 reduce the Young’s modulus so that a large time step is applicable. The difference between them is one with reduced contact radius ($c=0.182$ in treatment 3), and another not ($c=1$ in treatment 2). The results are shown in Fig. 10. The convective heat transfer coefficient is not affected by those treatments (Fig. 10a). Particle-particle contact only affects the conduction heat transfer (Fig. 10b). The results are very comparable and consistent between the models using treatments 1 and 3, but they are quite different from the model using the treatment 2. If the particle thermal conductivity is high, such difference becomes even more significant. The comparison in Fig. 10b indicates that the modified model by treatment 3 can be used in the study of heat transfer not only in packed beds but also in fluidization beds. It must be pointed out that the significance of proposed modified
model (treatment 3) is to save computational cost. For the current case shown in Fig. 10, the use of a low Young’s modulus significantly reduces the computational time, i.e. 4~5 times faster with 16,000 particles. Such a reduction becomes more significant for a larger system involving a large number of particles.

### 3.3 Heat transfer between a fluidized bed and an insert tube

Immersed surfaces such as horizontal/vertical tubes, fins and water walls are usually adopted in a fluidized bed to control the heat addition or extraction (Chen, 1998). Understanding the flow and heat transfer mechanisms is important to achieve its optimal design and control (Chen et al., 2005). The relation of the HTC of a tube and gas-solid flow characteristic in the vicinity of the tube such as particle residence time and porosity has been investigated experimentally using heat-transfer probe and positron emission particle tracking (PEPT) method or an optical probe (Kim et al., 2003; Wong & Seville, 2006; Masoumifard et al., 2008). The variations of HTC with probe positions and inlet gas superficial velocity are interpreted mechanistically. The observed angular variation of HTC is explained by the PEPT data.

Alternatively, the DPS-CFD approach has been used to study the flow and heat transfer in fluidization with an immersed tube in the literature (Wong & Seville, 2006; Di Maio et al., 2009; Zhao et al., 2009). Di Maio et al. (2009) compared different particle-to-particle heat transfer models and suggested that the formulation of these models are important to obtain comparable results to the experimental measurements. Zhao et al. (2009) used the unstructured mesh which is suitable for complex geometry and discussed the effects of particle diameter and superficial gas velocity. They obtained comparable prediction of HTC with experimental results at a low temperature. These studies show the applicability of the proposed DPS-CFD approach to a fluidized bed with an immersed tube. However, some important aspects are not considered in these studies. Firstly, their work is two dimensional with the bed thickness of one particle diameter. But as laterly pointed out by Feng and Yu (2010), three dimensional bed is more reliable to investigate the structure related...
phenomena such as heat transfer. Secondly, the fluid properties such as fluid density and thermal conductivity are considered as constants. However, the variations of these properties have significant effect on the heat transfer process (Botterill et al., 1982; Pattipati & Wen, 1982). Thirdly, although the particle-particle heat transfer has proved to be critical for generation of sound results (Di Maio et al., 2009), the heat transfer through direct particle contact in these works simply combined static and collisional contacts mechanisms together, which are two important mechanisms particularly in a dynamic fluidized bed (Sun & Chen, 1988; Zhou et al., 2009). Finally, the radiative heat transfer mechanism is ignored, which is significant in a fluidized bed at high temperatures (Chen & Chen, 1981; Flamant & Arnaud, 1984; Chung & Welty, 1989; Flamant et al., 1992; Chen et al., 2005).

Recently, Hou et al. (2010a; 2010b) used the proposed DPS-CFD model to investigate the heat transfer in gas fluidization with an immersed horizontal tube in a three dimensional bed. The simulation conditions are similar to the experimental investigations by Wong and Seville (2006) except for the bed geometry. The predicted result of 0.27 m/s for minimum fluidization velocity ($u_{mf}$) is consistent with those experimental measurements (Chandran & Chen, 1982; Wong & Seville, 2006). Fig. 11 shows the snapshots of flow patterns obtained from the DPS-CFD simulation. The bubbling fluidized bed behaviour is significantly affected by the horizontal tube. Two main features can be identified: defluidized region in the downstream and the air film in the upstream (Glass & Harrison, 1964; Rong et al., 1999; Wong & Seville, 2006). Particles with small velocities tend to stay on the tube in the downstream and form the defluidized region intermittently. The thickness of the air film below the tube changes with time. There is no air film and the upstream section is fully filled with particles at some time intervals (e.g. $t = 1.3$ s and 3.0 s in Fig. 11).

![Fig. 11. Snapshots of solid flow pattern colored by coordination number of individual particles when $u_{exc} = 0.50$ m/s (Hou et al., 2010a).](image_url)

The tube exchanges heat with its surrounding particles and fluid. The local HTC has a distribution closely related to these observed flow patterns. The distribution and magnitude of HTC are two factors commonly used to describe the heat transfer in such a system (Botterill et al., 1984; Schmidt & Renz, 2005; Wong & Seville, 2006). The effect of the gas velocity and the tube position are examined, showing consistent results with those reported in the literature (Botterill et al., 1984; Kim et al., 2003; Wong & Seville, 2006) (Fig. 12).
local HTC is high at sides of the tube around 90° and 270° while it is low at the upstream and downstream of the tube around 0° and 180°. With the increase of gas velocity, the local HTC increases first and then decreases (Fig. 12a). The local HTC is also affected by tube positions, and increases with the increase of tube level within the bed static height as shown in Fig. 12b.

![Fig. 12. Comparison of local HTCs between the predicted (Hou et al., 2010a) and the measured (Wong & Seville, 2006): (a) local HTC distribution at different excess gas velocities (u_{exc}) (○, 0.08 m/s; ◊, 0.50 m/s; and Δ, 0.80 m/s); and (b) local HTC with different tube positions when u_{exc} = 0.20 m/s.](image)

![Fig. 13. (a) Overall convective and conductive heat fluxes (q) and their percentages (--; convection; ·····, conduction), overall contact number (CN) and overall porosity (ε) as a function of time, where u_{exc} = 0.40 m/s (the overall heat flux and CN are the sum of the corresponding values of each section and the overall porosity are the averaged value of all the sections), and (b) local porosity and CN with different u_{exc} (Hou et al., 2010a).](image)
The heat is mainly transferred through convection between gas and particles and between gas and the tube, and conduction among particles and between particles and the tube at low temperature. As an example, Fig. 13a shows the total heat fluxes through convection and conduction (the radiative heat flux is quite small at low temperatures and is not discussed here). The convective and conductive heat fluxes vary temporally. Their percentages show that the convective heat transfer is dominant with a percentage over 90%. They are closely related to the microstructure around the tube, which can be indexed by the average porosity around the tube and by the contact number (CN) between the tube and the particles. The porosity and CN vary temporally depending on the complicated interactions between the particles and the tube and between the particles and fluid, which determine the flow pattern. Generally, a region with a larger CN corresponds to a defluidized region with a smaller porosity in the vicinity of the tube. Otherwise, it corresponds to a passing bubble where the porosity is larger and the CN is smaller. Fig. 13b further shows the distribution of local porosity and CN. It can be seen that local porosity is larger in downstream sections and lower in upstream sections while local CN has an opposite distribution.

The heat transfer between an immersed tube and a fluidized bed depends on many factors, such as the contacts of particles with the tube, porosity and gas flow around the tube. These factors are affected by many variables related to operational conditions. Gas velocity is one of the most important parameters in affecting the heat transfer, which can be seen in Fig. 12. With the increase of $u_{exc}$ from 0.08 to 0.50 m/s, the overall heat transfer coefficient increases. However, when the $u_{exc}$ is further increased from 0.50 to 0.80 m/s, the heat transfer coefficient decreases. The effect of particle thermal conductivity $k_p$ on the local HTC was also examined and shown in Fig. 14a (Hou et al., 2010a). The local HTC increases with the increase of $k_p$ from 1.10 to 100 W/(m·K). However, such an increase is not significant for $k_p$ from 100 to 300 W/(m·K). The variations of percentages of different heat transfer modes with $k_p$ is further shown in Fig. 14b. When $k_p$ is lower than 100 W/(m·K), the conductive heat transfer increases with the increase of $k_p$ while the convective heat transfer decreases. Further increase of $k_p$ has no significant effects.

![Fig. 14. Effect of $k_p$ on: (a), local HTC; and (b), percentages of different heat fluxes; where $u_{exc} = 0.50$ m/s (Hou et al., 2010a).](www.intechopen.com)
the literature (see, for example, Mathur & Saxena, 1987; Chen et al., 2005). The effect of the tube temperature ($T_s$) on heat transfer characteristic was investigated in terms of the local HTC distribution and the heat fluxes by different heat transfer modes (Hou et al., 2010a). Fig. 15a shows that the local HTC increase with the increase of $T_s$. The increased trend of HTC agrees well with the results of the experiments (Botterill et al., 1984). The increase of gas thermal conductivity with temperature is one of the main reasons for the increase of HTC (Zhou et al., 2009). This manifests the importance of using the temperature related correlations of fluid properties. Variations of the heat fluxes with tube temperature $T_s$ are shown in Fig. 15b. The conductive heat flux changes insignificantly. The convective heat flux increases linearly while the radiative heat fluxes increases exponentially with the increase of the $T_s$. Because of the increase of $T_u$, the difference between the environmental temperature ($T_e$) and the bed temperature ($T_b$) increases. The radiative heat flux increases more quickly than the convective heat flux according to the fourth power law of the temperature difference. The radiative heat flux becomes larger than that of conductive heat flux around $T_s = 300^\circ C$ and then, larger than that of the convective heat flux around $T_s = 1200^\circ C$. These show that the radiation is an important heat transfer mode with high tube temperatures.

![Image](Fig. 15. Heat transfer behaviour at high tube temperatures: (a), variations of local HTC with different $T_s$, where $h_{exc} = 0.50$ m/s; and (b), convective, conductive, radiative and total heat fluxes as a function of $T_s$, where $h_{exc} = 0.50$ m/s (Hou et al., 2010a).)

4. Conclusions

The DPS-CFD approach, originally applied to study the particle-fluid flow, has been extended to study the heat transfer in packed and bubbling fluidized beds at a particle scale. The proposed model is, either qualitatively or quantitatively depending on the observations in the literature, validated by comparing the predicted and measured results under different conditions. Three basic heat transfer modes (particle-fluid convection, particle conduction and radiation) are considered in the present model, and their contributions to the total heat transfer in a fixed or fluidized bed can be quantified and analyzed. The examples presented demonstrate that the DPS-CFD approach is very promising in quantifying the role of various heat transfer mechanisms in packed/fluidized beds, which is useful to the optimal design and control of fluid bed reactors.

Over the past few decades there has been a prolific increase in research and development in area of heat transfer, heat exchangers and their associated technologies. This book is a collection of current research in the above mentioned areas and describes modelling, numerical methods, simulation and information technology with modern ideas and methods to analyse and enhance heat transfer for single and multiphase systems. The topics considered include various basic concepts of heat transfer, the fundamental modes of heat transfer (namely conduction, convection and radiation), thermophysical properties, computational methodologies, control, stabilization and optimization problems, condensation, boiling and freezing, with many real-world problems and important modern applications. The book is divided in four sections: "Inverse, Stabilization and Optimization Problems", "Numerical Methods and Calculations", "Heat Transfer in Mini/Micro Systems", "Energy Transfer and Solid Materials", and each section discusses various issues, methods and applications in accordance with the subjects. The combination of fundamental approach with many important practical applications of current interest will make this book of interest to researchers, scientists, engineers and graduate students in many disciplines, who make use of mathematical modelling, inverse problems, implementation of recently developed numerical methods in this multidisciplinary field as well as to experimental and theoretical researchers in the field of heat and mass transfer.
