Finger Vein Recognition

Kejun Wang, Hui Ma, Oluwatoyin P. Popoola and Jingyu Li

Pattern Recognition & Intelligent Systems Department, College of Automation, Harbin Engineering University, China

1. Introduction

Smart recognition of human identity for security and control is a global issue of concern in our world today. Financial losses due to identity theft can be severe, and the integrity of security systems compromised. Hence, automatic authentication systems for control have found application in criminal identification, autonomous vending and automated banking among others. Among the many authentication systems that have been proposed and implemented, finger vein biometrics is emerging as the foolproof method of automated personal identification. Finger vein is a unique physiological biometric for identifying individuals based on the physical characteristics and attributes of the vein patterns in the human finger. It is a fairly recent technological advance in the field of biometrics that is being applied to different fields such as medical, financial, law enforcement facilities and other applications where high levels of security or privacy is very important. This technology is impressive because it requires only small, relatively cheap single-chip design, and has a very fast identification process that is contact-less and of higher accuracy when compared with other identification biometrics like fingerprint, iris, facial and others. This higher accuracy rate of finger vein is not unconnected with the fact that finger vein patterns are virtually impossible to forge thus it has become one of the fastest growing new biometric technology that is quickly finding its way from research labs to commercial development. Historically, R&D at Hitachi of Japan (1997-2000) discovered that finger vein pattern recognition was a viable biometric for personal authentication technology and by 2000-2005 were the first to commercialize the technology into different product forms, such as ATMs. Their research reports false acceptance rate (FAR) of as low as 0.0001 % and false reject rate (FRR) of 0.1%. Today 70% of major financial institutions in Japan are using finger vein authentication.

Fig. 1. Hitachi of Japan history of research & development on finger-vein recognition technology
Fingerprints have been the most widely used and trusted biometrics. The reasons being: the ease of acquiring fingerprints, the availability of inexpensive fingerprint sensors and a long history of its use. However, limitations like the deterioration of the epidermis of the fingers, finger surface particles etc result in inaccuracies that call for more accurate and robust methods of authentication. Vein recognition technology however offers a promising solution to these challenges due the following characteristics. (1) Its universality and uniqueness. Just as individuals have unique fingerprints, so also they do have unique finger vein images. The vein images of most people remain unchanged despite ageing. (2) Hand and finger vein detection methods do not have any known negative effects on body health. (3) The condition of the epidermis has no effect on the result of vein detection. (4) Vein features are difficult to be forged and changed even by surgery [1]. These desirable properties make vein recognition a highly reliable authentication method.

Vein object extraction is the first crucial step in the process. The aim is to obtain vein ridges from the background. Recognition performance relates largely to the quality of vein object extraction. The standard practice is to acquire finger vein images by use of near-infrared spectroscopy. When a finger is placed across near infra-red light rays of 760 nm wavelength, finger vein patterns in the subcutaneous tissue of the finger are captured because deoxygenated hemoglobin in the vein absorb the light rays. The resulting vein image appears darker than the other regions of the finger, because only the blood vessels absorb the rays. The extraction method has a direct impact on feature extraction and feature matching [2]. Therefore, vein object extraction significantly affects the effectiveness of the entire system.

2. Processing

After vein image extraction, comes segmentation. The traditional vein extraction technology can be classified into three broad categories according to their approach to segmentation i.e separating the actual finder veins from the background and noise. There are those based on region information, those based on edge information, and those based on particular theories and tools. However, the application of the traditional single-threshold segmentation methods such as fixed threshold, total mean, total Otsu to perform segmentation, faces limitations in obtaining the desired accurate segmentation results. Using multi-threshold methods like local mean and local Otsu, improve these results but still cannot effectively deal with noise and over-segmentation effects [3], [4], [5], [6], [7],[8]. In a related research, reference [9] proposed an oriented filter method to enhance the image in order to eliminate noise and enhance ridgeline. Authors in [10] used the directionality feature of fingerprint to present a fingerprint image enhancement method based on orientation field. These two methods take the directionality characteristic of fingerprints into account, so they can enhance and de-noise fingerprint images effectively. Finger vein pattern also has textural and directionality features, with directionality being consistent within the local area. Inspired by methods in [9] and [10], we discuss in this chapter, finger vein pattern extraction methods using oriented filtering from the directionality feature of veins. These utilize the directionality feature of finger vein images using a group of oriented filters, and then extracting the vein object from an enhanced oriented filter image.

www.intechopen.com
2.1 Normalization
Normalization is a pixel-wise operation often used in image processing. The main purpose of normalization is to get an output image with desirable mean and variance, which facilitates the subsequent processing. The uniformly illuminated image becomes normalized by this formula:

\[
M = \frac{1}{M \times N} \sum_{i=0}^{M-1} \sum_{j=0}^{N-1} I(i,j)
\]

\[
VAR = \frac{1}{M \times N} \sum_{i=0}^{M-1} \sum_{j=0}^{N-1} (I(i,j) - M(I))^2
\]

\[
G(i,j) = \begin{cases} 
M_o + \frac{VAR}{\sqrt{VAR}}(I(i,j) - M)^2, & I(i,j) \geq M \\
M_o - \frac{VAR}{\sqrt{VAR}}(I(i,j) - M)^2, & I(i,j) < M 
\end{cases}
\]

Where \( M \) and \( VAR \) denote the estimated mean and variance of input image and \( M_o = 150, VAR_o = 255 \) are desired mean and variance values respectively. After normalization, the output image is ready for next processing step. The result of the above-mentioned process is shown in Fig.2. We note that Fig.2 image has lost some of its contrast but now has uniform illumination.

---|---
Fig. 2. Original image and Normalized image

2.2 Oriented filter enhancement
Finger vein pattern has directionality characteristics, which the traditional filter methods do not take into account; therefore, its resultant filtering enhancement is not satisfactory. We propose a vein pattern extraction method using oriented filtering technology that takes into account the directionality feature of the veins. This algorithm utilizes a group of oriented filters to filter the image depending on the orientation of the local ridge.
a. Calculation of directional image

The directional image is an image transform, where we use the direction of every pixel of an image to represent the original vein image. Pixels’ direction refers to the orientation of continuous gray value. We can determine the direction of pixel according to the gray distribution of the neighborhood. Pixels along the vein ridge have minimum gray level difference while pixels perpendicular to the vein ridge have the maximum gray level difference.

To estimate the orientation field of vein image, the direction of the vein is quantized into eight directions. Using a \(9 \times 9\) template window as shown in Fig.2, we choose reference pixel \(p(i, j)\) the center of the direction template. The values 1-8 of the template correspond to eight directions rotating from 0 to \(\pi\). Each interval has an angle of \(\pi/8\) in an anti-clockwise direction from the horizontal axis.

The main steps of the method are:

1. For every pixel, use the \(9 \times 9\) rectangular window (shown as Fig.2) to obtain the pixel gray value average \(M_i\) \((i = 1, 2...8)\).
2. Divide \(M_i\) \((i = 1, 2...8)\) into four groups. \(M_1\) and \(M_3\) are perpendicular in direction, so they belong to the same group. For the same reason, \(M_2\) and \(M_4\), \(M_5\) and \(M_6\), and \(M_7\) and \(M_8\) belong to the same group. In each group, calculate \(\Delta M\) - the absolute difference between two gray value averages \(M_j\) and \(M_{j+4}\).

\[
\Delta M = |M_j - M_{j+4}|, j = 1, ..., 4
\]  

(4)

where \(j\) is the direction of the vein.

3. Choose the maximum \(\Delta M\) to determine the pixel’s possible directions \(j_{\text{max}}\) and \(j_{\text{max}} + 4\).

4. Determine the actual direction of \(p(i, j)\) by comparing its gray value with the gray value averages of \(j_{\text{max}}\) and \(j_{\text{max}} + 4\). The closer value is its direction. Therefore, the pixels direction is given by:

\[
D(x, y) = \begin{cases} 
  j_{\text{max}} \text{ if } |M - M_{j_{\text{max}}} + 4| < |M - M_{j_{\text{max}} + 4}| \\
  j_{\text{max}} + 4, \text{ otherwise}
\end{cases}
\]  

(5)

When the above process is performed on each pixel in the image, we can obtain the directional image \(D(x, y)\) of the vein image. Due to the presence of noise in the vein image, the estimated orientation field may not always be correct. In a small local neighborhood, the pixels’ orientations are generally uniform; and so a local ridge orientation is specified for a block rather than at every pixel. Using a smoothing process on the point directional map, a continuous directional map is obtained. A continuous \(w \times w\) window can be used to modify the incorrect ridge orientation and smooth the point directional map. The experiments show that \(w = 8\) is very good. We obtain each window’s directional histogram and choose the peak value of the direction histogram as \(P(x, y)\)’s orientation. The continuous directional map \(O(x, y)\) is defined as:

\[
O(x, y) = \text{ord}(\max(N_i))
\]  

(6)
The directional image of finger vein is as shown in Fig. 3. Each color of directional image corresponds to a direction. As can be seen from the Fig. 4, vein ridge has the feature of directionality, and the vein ridge orientation varies slowly in a local neighborhood.

b. Oriented filter

The vein directional image is a kind of textured pattern generated by using oriented filters based on directional map to enhance the original images. We designed eight filter masks, each one associated with the discrete ridge orientation of finger vein pixels. From the direction determined for a specific block (from the original image), a corresponding filter is selected to enhance this block image. The template coefficients of horizontal mask are designed first. To generate the seven other masks, the horizontal filter mask is rotated according to the direction of the vein. O’Gorman’s rules for filter design which is described for enhancing fingerprint images consists of four key points:

1. An appropriate filter template size.
2. The width of the filter template should be odd in order that the template is symmetric in the direction of horizontal and vertical.
3. In the vertical direction, central part of the filter template coefficient should be positive while both sides of the coefficient negative.
4. The sum of all template coefficients should be zero.

Applying the above rules based on the direction of the finger vein, we modify the filter’s coefficients so that they decay from the center to both ends of the template. The oriented filter’s size is decided according to vein ridge width. From experiments, a filter template of size 7 has been shown to be quite effective.
The coefficient spatial arrangement of the horizontal mask is shown in Fig. 5. 

(a) The coefficients of the filter template should meet the following given conditions:
\[ d + 2a + 2b - 2c = 0, \text{ where } d > a > d \geq 0, c > 0; \]
An example of oriented filter is shown as Fig. 5 (b). Now, aiming at every pixel \((i, j)\) in the input image, we select a 3 neighborhood that takes \((i, j)\) as the center. It is filtered with the mask that corresponds to the block orientation of the center \((i, j)\). This filtering technique is given by:

\[
f(i, j) = \sum_{x=-3}^{3} \sum_{y=-3}^{3} G(i + x, j + y)g_\theta(x, y)
\]

where \((i, j)\) represents the pixel of original image, and \(x, y\) represents the size of oriented filter template and \(g_\theta(x, y)\) represents the corresponding coefficients of the template. \(T_x\) represents the filtered image. It is possible that some gray values fall outside the \([0, 255]\) range. Equation (8) is used to adjust the gray values to fall within the range.

\[
f'(i, j) = \text{Round}\left(\frac{f(i, j) - f_{\text{min}}(i, j)}{f_{\text{max}}(i, j) - f_{\text{min}}(i, j)} \times 255\right)
\]

Where \(f(i, j)\) represents the original gray of \((i, j)\), \(f_{\text{min}}(i, j)\) represents smallest gray value of original image, \(f_{\text{max}}(i, j)\) represents biggest gray value of original image. \(f'(i, j)\) represents transformed gray of \((i, j)\) and \(\text{Round}(.)\) is a rounding function.

To generate the other seven masks, we rotate the horizontal filter mask according to the following equation: Where \((i, j)\) represents the coordinates in the horizontal mask, and \((i', j')\) represents the ones in the rotated mask.

\[
\begin{bmatrix}
i' \\
j'
\end{bmatrix} = \begin{bmatrix}
\cos \theta & \sin \theta \\
-\sin \theta & \cos \theta
\end{bmatrix} \begin{bmatrix}
i \\
j
\end{bmatrix}
\]

Where \(\theta = (d - 1) / \pi, d = 1, 2, ..., 8\), \(\theta\) represents the rotation angel, and \(d\) represents the direction value of \((i, j)\).

To use this method, \((i, j)\) is usually not an integer, so we need to use nearest neighbor interpolation to get the coefficients of the rotated mask. \(g_\theta(i', j')\) (the coefficients in the rotated mask) is equal to \(g_\theta(i, j)\) (the coefficients in the horizontal mask).
Suppose the four points \((i_n, j_n), (i_r, j_r), (i_s, j_s), (i_t, j_t)\) compose a square centered at pixel \((i, j)\), and \(g_a(i_n, j_n), g_b(i_n, j_n), g_c(i_r, j_r), g_d(i_s, j_s)\) are their corresponding coefficients in the horizontal mask, where \(i_n < i < i_r, j_n < j < j_r\).

First, make interpolation between \((i_n, j_n)\) and \((i_r, j_r)\):

\[
g(i, j) = g_a(i_n, j_n) + (i - i_n) \times [g_b(i_n, j_n) - g_a(i_n, j_n)]
\]

Then make interpolation between \((i_n, j_n)\) and \(\alpha\):

\[
g(i, j) = g_a(i_n, j_n) + (i - i_n) \times [g_b(i_n, j_n) - g_a(i_n, j_n)]
\]

Finally, make interpolation between \(a_n\) and \(b_n\):

\[
g_d(i', j') = g(i, j_n) + (j - j_n) \times [g(i, j_s) - g(i, j_n)]
\]

Once we have all eight filter masks, their coefficients can be used to enhance vein image.

### 2.3 Image segmentation

NiBlack segmentation method is a commonly used simple and effective local dynamic threshold algorithm, so we choose this method to segment the image. The basic idea of this algorithm is that for every pixel in the input image, calculate their mean and variance of its \(r \times r\) neighborhood. Then the result of the following formula is used as threshold to segment image.

\[
T(x, y) = m(x, y) + k \times s(x, y)
\]

![Image enhanced by oriented filter](image1.png)

Fig. 6(a). Image enhanced by oriented filter

![Image after segmentation and noise removal](image2.png)

Fig. 6(b). Image after segmentation and noise removal

Where \((x, y)\) represents pixel in the input image, \(T(x, y)\) represents the threshold of \(\forall a, a' \in M, a = H(x) = T_p(T_a(a))\) represents the mean value of \(a_n = T_p^{-1}(T_p^{-1}(a))\)'s \(r \times r\) neighborhood, and \(s(x, y)\) represents the standard deviation of \(v(a') = v(a)\)'s \(a_n = T_p(v(a_n))\) neighborhood, \(k\) is a correction coefficient. The experiments show that \(v(a) = T_p(v(a_n))\) equal to 9 and \(v(a_n) = T_p^{-1}(v(a'))\) equal to 0.01 is excellent. There are some
small black blocks in the background and some small white holes on the target object in the segmented image. Such noise can be removed with area elimination method. Because of variability in image acquisition and the inherent differences in individual samples, the size and ratios of extracted finger veins are often inconsistent. In order to facilitate further research there is a need for standardization of the segmented vein image height (and width). The normalized image is shown in Fig.7. In the experiment, we have standardized the height of the image to 80 pixels.

Fig. 7. Standardized finger vein image width

Accurate extraction of finger vein pattern is a fundamental step in developing finger vein based biometric authentication systems. The finger vein pattern extraction method proposed and discussed above extends traditional image segmentation methods, by extracting vein object from the oriented filter enhanced image. The addition of oriented filter operation extracts smooth and continuous vein features from not only high quality vein images but also noisy low quality images and does not suffer from the over-segmentation problem.

3. Feature extraction, fusion and matching

Finger vein recognition as a feature for biometric recognition has excellent advantages such as being stable, contactless, unique, immune to counterfeiting, highly accurate etc. This makes finger-vein recognition widely considered as the most promising biometric technology for the future. Naoto Miura [14] proposed one method for finger-vein recognition based on template matching. In the experiment, the finger-vein image is first binarized, and then using a distance transform noise is removed, and embedded hidden Markov model is used for finger-vein recognition. This approach is time intensive, and another major limitation is that it cannot recognize distorted finger-vein images correctly. Kejun Wang [15] combined wavelet moment, PCA and LDA transform for finger-vein recognition. Here the metric of finger-vein image is converted to a one-dimensional vector, which has been reduced dimensionally. To deal with the problem of high dimensionality, researchers usually first partition the finger-vein image and then principal component analysis (PCA) is applied. To date, this has been the most popular method for dimensionality reduction in finger-vein recognition research. Xueyan Li [16] proposed a method, which combines two-dimensional wavelet and texture characteristic, to recognize the finger vein while Xiaohua Qian [17] used seven moment invariant finger vein features. Euclidean distance and a pre-defined threshold were used as the classifying criterion for matching and recognition. Chengbo Yu [13] defined valley regions as finger vein features such that real features could not be missed and the false features would not be extracted. Zhongbo Zhang [18] proposed an algorithm based wavelet and neural network, which extracts features at multi-scale. Zhang's algorithm can capture features from degraded images.
3.1 Novel finger vein recognition methods based using fusion approach

The above-mentioned algorithms have different advantages for different problems in finger-vein recognition. However, because fingers have curved surfaces, finger vein diameter is not consistent and the texture characteristic is aperiodic. When near infrared light is used to acquire the image, the gray-scale is uneven and contrast is low; besides, finger veins are tiny and few in number, such that only very few features can be extracted. What is more, a change in the finger position can cause image translation and rotation and influence recognition negatively. To deal with these problems some novel fusion methods are used. First, we discuss a method based on relative distance and angle. This approach makes full use of the uniqueness of topology, the varied distances between the intersection points of two different vein images, and the differences in angles produced by these intersection points connections, all combined for recognition. This method overcomes the influence of image translation and rotation, because relative distance and angle don’t change. Therefore, the method based on these identified characteristics has great use in practice.

3.1.1 Theoretical basis

Let \( a, b, \) and \( c \) be non-zero vectors. \( \theta \) is the angle between two vectors, and the length of line segment is written as \( ||a|| \). The thinned finger-vein image is illustrated as a function denoted as \( M \), which is defined in field \( D \); where \( M \) is a subset of \( D \). Image translation and rotation occurs in \( D \). Image translation and rotation implies that every point of the image is translated by a vector \( s \) and rotated by the some angle. The relative distances and angles remain constant before and after translation and rotation, which is proved as follows.

The topology produced by all the character point connections can be called the image \( M \). Then \( M \) can be shown by the vectors: 

\[
\{a_0, a_1, \ldots, a_n\}
\]

Let \( a[s] = \{a_0, a_1, \ldots, a_n\} \), were \( a[s] \) denotes a vector \( a \), translated by \( s \) unit distances. If \( g_s = <a, a[s]> \), where \( <a, b> \) denotes the inner product of \( a \) and \( b \); and \( v(a) = (g_0, g_1, \ldots, g_{n-1}) \), where \( v(a) \) is the convolution of \( a \).

Now after image \( M \) is translated by \( s \) unit distances in the plane \( D \), we get the image \( M' = M[s] \).

A random translation of image \( M \) is translated by \( T_s \), is \( T_s(a) = a[s], (0 \leq s \leq n) \).

**Theorem 1.** Suppose \( T_s \) is a translation in \( D \), then \( v(a) = v(T_s(a)) \).

**Proof:** \( \forall s, t \in N \), there is

\[
<a[t], a[s + t]> = <a[t], a[s]>
\]

(14)

\[
\exists <a[t], a[s + t]> = \sum_i a_i[t]a_i[s + t] = \sum_i a_i[0]a_i[s] = \sum_i a_i[0][s] = <a[0], a[s]>
\]

From formula (14), we know \( \forall s, t \in N \), \( g_s(a[t]) = g_s(a) \) which satisfies

\[
v(a[t]) = v(a)
\]

(15)

For every \( T_s \), \( \exists T_s(a) = a(s) \) which leads to \( v(a) = v(a[s]) = v(T_s(a)) \).

**Theorem 2.** After transformation, the relative distances and angles produced by the character point connections are in unchanged.
Proof: In the plane $D$, $\forall\ a_0, b_0, c_0 \in M$ denotes the line segment vector produced by character point connections. $\theta_0$ is the angle of $a_0$ and $b_0$. Any angle $\alpha$, makes the image $M$ rotate around its ordinate origin by $\alpha$.

($\alpha$ is positive while clockwise, and negative otherwise), which is a linear transform $T_\alpha$. This results in image $\overline{M}$. For $\forall\ a$ and $b$, there is

$$[a, b] = [a_0, b_0] \ T_\alpha = [a_0, b_0] \begin{bmatrix} \cos \alpha & \sin \alpha \\ -\sin \alpha & \cos \alpha \end{bmatrix}$$

(16)

Here $[a, b]$ is a homogeneous orthogonal rotated matrix, and $\|T_\alpha\| = \sqrt{\rho(T_\alpha^T T_\alpha)} = 1$, $\rho(\cdot)$ is the matrix radius. Then we can write

$$\|a\| = \sqrt{a^T a} = \sqrt{a_0^T T_\alpha^T T_\alpha a_0} = \|a_0\|.$$

Accordingly,

$$\|b\| = \|b_0\|$$

(17)

$$<a, b> = <T_\alpha a_0, T_\alpha b_0> = \|T_\alpha a_0\| <a_0, b_0>$$

This leads to

$$\theta = \arccos \frac{<a, b>}{\|a\| \|b\|} = \theta_0$$

(18)

Theorem 3. The relative distances and angles are invariable after the translation and rotation

Proof: Suppose the image $M$ converts to $M'$ after translation by $T_x$ and rotation by $T_\alpha$. $\forall\ a, a' \in M'$, suppose $a = H(x) = T_x(T_\alpha(a_0))$, then $a_0 = T_\alpha^{-1}(T_\alpha(a))$. Suppose, too, $a' = T_\alpha^{-1}(a)$, then $a_0 = T_\alpha^{-1}(a')$. From theorem 1, we know $v(a') = v(a)$, further because of $a_0 = T_\alpha(v(a'))$ and $v(a) = T_\alpha(v(a_0))$, so $v(a_0) = T_\alpha^{-1}(v(a'))$. All this leads up to

$$v(a_0) = v(H(a_0))$$

(19)

### 3.1.2 Method description

Extract the intersecting points from the repaired thinned finger-vein image and connect all the points with each other. Compute the relative distances and angles to get the relative distance feature $M$, and the angle feature $\theta$. Fuse these two features by "Logical And", and on this basis, match any two images to get the number of relative distances and angles that correlate. Only when both features are approximately the same, is the matching successful. Otherwise, the matching has failed.

#### A. Finger vein topology

Using Kejun Wang’s method [19] for pre-processing hand-back vein image, combined with region merging and watershed algorithm, the finger-vein skeleton is extracted, thinned and further repaired. A fully meshed topology is formed by selecting the intersecting points on the thinned finger-vein image as character points and connecting these points to each other with straight lines, partitioning the image into several regions as shown in Fig.8.
In Fig. 8, (i) and (ii) are two finger-vein images from the same source, so their topology is similar. However, (iii) is from a different source and its topology is obviously different from (i) and (ii). Specifically, the topology expresses an integral property and peculiarity of finger-veins, the relationship between corresponding character points is of importance.

3.1.3 Matching finger-vein images using relative distance and angles

From the thinned finger-vein image of Fig.8 (b), we can see the random finger-vein pattern and inner structure. The inner characteristic points produced by the intersecting vein crossings reflect the unique property of the finger-vein. However, those breakpoints may be thought as finger-vein endpoints, which would influence recognition results. For this reason, the more reliable intersecting points are chosen to characterize finger-veins. Considering that different line segments are produced by intersecting points from different finger-vein images, the two features - relative distance and angle - are combined for matching.

Relative distance and angle are essential attributes of finger-veins, which ensure the feature uniqueness and reflect different characteristics of finger-vein structure. Fusion of the two
features with “Logical And” make the recognition results more reliable. Thus, matching two finger-vein images is converted into matching the similarity of topologies. The detailed steps are as follows.

1. Calculate the relative distances and angles of finger-vein image. Suppose, there are \(d\) points of intersection in one image, then the number of relative distance is \(d(d-1)/2\). The number of angles produced by the point connections is \(d(d-1)(d-2)/2\). Here a set of finger-vein image features is defined as \(R=(l_m,\theta_u)\), where \(l\) is the distance of any two intersecting points, \(\theta\) is the angle produced by the point connections, \(m\) and \(u\) are the number index respectively. Suppose, \(R_1=(l_{m_1},\theta_{u_1})\) and \(R_2=(l_{m_2},\theta_{u_2})\) are two sets of finger-vein image features.

2. Compare \(m\) relative distances from \(R_1\) with \(n\) relative distances from \(R_2\), by calculating the number of approximately similar relative distances. If the number is greater than the pre-defined threshold, go to next step; else, the matching is assumed to have failed. To take care of position error of those points, we define \(|l_m-l_n|<e\) to show the extent of similarity between any two Eigen values \((e\) is the allowable error range). From experimental analysis, \(e=0.0005\) is very appropriate.

3. Suppose there are \(q\) eigenvalues of approximately equivalent relative distances, connect the \(q\) character points in the two sets respectively, with each other. Thus, \(z\) angles are produced, which are denoted as \(\theta_{z_1}\) and \(\theta_{z_2}\) in \(R_1\) and \(R_2\) respectively. On this basis, calculate the number of approximately equivalent angles. If the number is greater than the pre-defined threshold, the matching is successful; else, the matching is thought to have failed. Similarly, \(|\theta_{z_1}-\theta_{z_2}|<e'\) is used to show the relationship of two approximately equivalent. From experimental analysis, \(e'=0.006°\) is very appropriate.

### 3.2 Finger vein recognition based on wavelet moment fused with PCA transform

#### 3.2.1 Finger vein feature extraction

Different people have different finger lengths. Also, there can be variation in the image captured for the same person due to positioning during the image capture process. Thus if image sizes are not standardized, there is bound to be representation error which leads to a decrease in the recognition rate. In this part, we resize the vein image into a specific image block size to facilitate further processing. The original image is standardized to a height of 80 pixels and split along the width into \(80 \times 80\) sub-image block size. If the image is split evenly (given that the image width is generally about 200 pixels) there will be loss of information that will affect recognition. Therefore, the sub-blocks are created with an overlap of 60 pixels for every \(80 \times 80\) image sub-block. The original image can thus be split into 6-7 sub-images, with sufficient characteristic quantities for identification.

Set a matrix \(A_{nxm}\) to represent the standardized images \(f(x,y)\).

\[
A_{nxm} = [A_{n1}, A_{n2}, ..., A_{n-1}]
\]  

(20)

Which: \(A_i\) is a column vector, \(i \in [0, n-1]\)

Here we define the sub-block of the image width \(w\), standardized image height \(h\) (in experiment \(w=80\), \(h=80\)). Sub-images are extracted at interval \(r\) when (in this experiment \(r=20\)).
Thus can get sub-image matrix:

\[
B_1 = \begin{bmatrix} a_0, \ldots, a_{w-1} \end{bmatrix}
\]

\[
B_2 = \begin{bmatrix} a_r, \ldots, a_{w-1+r} \end{bmatrix}
\]

...  

\[
B_k = \begin{bmatrix} a_{kr}, \ldots, a_{w-1+kr} \end{bmatrix}
\]

Thus we get a total of \( B_1, B_2, \ldots, B_k \) sub-image, and the size of each sub-image is \( w \times h \).

Then we extract features for each sub-image \( B_k \). The finger block, feature extraction and recognition process shown in Fig.12.

![Fig. 12. The sketch map of sub-image extraction](www.intechopen.com)

### 3.2.2 Wavelet transform and wavelet moments extraction

Wavelet moment is an invariant descriptor for image features. A wavelet moment feature is invariant to image rotation, translation and scaling so it is successfully applied in the pattern recognition.

For each sub-image \( B_k(x,y) \), its size is \( w \times h \). Applying two-dimensional Mallat decomposition algorithm, we can make wavelet decomposed image \( B_k(x,y) \).
Fig. 13. The sub-image and result of wavelet decomposition

Setting \( f(x, y) = B_i(x, y) \in L^2(\mathbb{R}^2) \) to be the analyzed sub-image vein blocks, the wavelet decomposed layer is

\[
f(x, y) = A_i + D_{i1} + D_{i2} + D_{i3}
\]

(22)

where \( A_i \) is the scale for the low frequency component (i.e. approaching component), and \( D_{i1}, D_{i2}, D_{i3} \) are the scales for the horizontal, vertical and diagonal components respectively.

\[
A_i = \sum_{(m,n)} c_i(m,n) \phi_i(m,n),
\]

(23)

\[
c_i(m,n) = \langle f(x,y), \phi_i(m,n) \rangle
\]

\[
D_{ik}(m,n) = \sum_{(m,n)} d_{ik}^i(m,n) \psi_i(m,n),
\]

(24)

\[
d_{ik}^i(m,n) = \langle f(x,y), \psi_i(m,n) \rangle
\]

Where \( k = 1,2,3 \) \( c_i = (m,n) \) is the coefficient of \( A_i \),
\( d_{ik}^i \) is the coefficient of the three high frequency components.
\( \phi_i(m,n) \) is the scale function
\( \psi_i(m,n) \) is the wavelet function

Daub4 was chosen for wavelet decomposition, as it produced better identification results from several experimental compared with other wavelets. We use the approximation wavelet coefficients \( c_i \) to compute the wavelet moment [4]. Set \( w_{p,q} \) expressed as \((p+q)\) order central moments of \( f(x,y) \). The wavelet moment approximation is:

\[
w_{p,q}^0 = 2^{-(p+q+1)} \sum_{m,n \in \mathbb{Z}} m^p n^q c_i(m,n)
\]

(25)

\[
w_{p,q}^k = 2^{-(p+q+1)} \sum_{m,n \in \mathbb{Z}} m^p n^q d_{ik}^i(m,n)
\]

Here we access the wavelet moment \( w_{22} \).

3.2.3 PCA transformation

The advantage of using wavelet transform to reduce computation is explored here. Using each sub-image \( B_i \) directly without the PCA transform not only leads to poor classification of extracted features but also huge computational cost. After the low-frequency wavelet sub-
images compression of the original image to about one-fourth of the original size, PCA decomposition is applied on the sub-image which greatly reduces computation.

### 3.2.4 The transformation matrix

Here we analyze a layer of $B_i$ wavelet decomposition of the low-frequency sub-image. For PCA, $A_i$ is transformed to a separate $wh/4$ dimension of image vector $\xi = \text{Vec}(A_i)$.

Five finger vein images per person (*same finger*)

Fig. 14. The sketch map of sample classes after PCA transform

To illustrate the problem, we take finger vein samples from a total set of $c$ people. Each sample of the same finger has five images as shown in Fig. 14. (Note that Fig.14 is only for illustration purpose. In practice, there is an interval of 20 pixels between two adjacent sub-blocks, and an overlap of 60 pixels as earlier described).

The $n$-th sub-block set of the $m$-th person is indexed as $k_{m,n}$; where $n = (1,2,3..., L)$; $L_m$ is the total number of sub-blocks for person $m$. 

www.intechopen.com
To compare images we only use the $k_{\text{min}}$ sub-image set where 

$$k_{\text{min}} = L = \min(L_1, L_2, L_3, \ldots, L_n)$$

when $k_{\text{min}} = 5$, then

$$k_{\text{min}} = \min(k_{1,1}, k_{1,2}, \ldots, k_{1,5}, k_{5,3}, k_{5,4})$$

(26)

Thus, a total of $C = c \times k_{\text{min}}$ of the available pattern classes, i.e. $\omega_1, \omega_2, \ldots, \omega_C$.

Four of the corresponding samples in the i-th class ($i = 5m + k$), $k = 1, 2, \ldots, k_{\text{min}}$ is the number of sub-image of each finger image, for simplicity, we write: $\xi_{i,1}, \xi_{i,2}, \xi_{i,3}, \xi_{i,5}$, and all are $wh/4$ dimension column vectors. The total number of training samples is $N = 5C$.

Mean of the i-th class training sample:

$$\bar{\xi}_i = \frac{1}{5} \sum_{j=1}^{5} \xi_{i,j}$$

(27)

Mean of all training samples:

$$\bar{\xi} = \frac{1}{N} \sum_{i=1}^{C} \sum_{j=1}^{5} \xi_{i,j}$$

(28)

The scatter matrix is:

$$S_i = \sum_{j=1}^{5} P(\omega_i) (\xi_{i,j} - \bar{\xi}_i)(\xi_{i,j} - \bar{\xi}_i)^T$$

(29)

where $P(\omega_i)$ is prior probability of the i-th class of training samples. Then we can obtain the characteristic value $\lambda_1, \lambda_2, \ldots, \lambda_d$ of $S_i$ (the value of these features have been lined up in sequence by order of $\lambda_1 \geq \lambda_2 \geq \ldots$) and its corresponding eigenvector $\phi_1, \phi_2, \ldots$. Take $d$ before the largest eigenvalue corresponding to the standard eigenvectors orthogonal transformation matrix $P = [\phi_1, \phi_2, \ldots, \phi_d]$. For each sub-image blocks $B_j$, through the wavelet decomposition of the low-frequency sub-image $A_1$, $A_1$ in accordance with the preceding method into a column vector $\xi_j$, to extract the features use the transformation matrix $P$ obtained in the previous section, the following formula:

$$e = P^T \xi_j$$

(30)

This $e = [e_1, e_2, \ldots, e_d]$ is the PCA extraction of feature vectors from sub-image blocks. After several experiments, we found that when $d = 200$ we can get a good result, and when $d = 300$ i.e a 300-dimensional compression, we get the best recognition results.

### 3.2.5 LDA map

In general, PCA method is the best for describing feature characteristics, but not the best for feature classification. In order to get better classification results, we use the LDA method for further classification of PCA features.

Each sample is transformed into a lower $d$-dimensional space in the post-dimensional feature vector $e_i = [e'_1, e'_2, \ldots, e'_d]$. Using PCA projection matrix $P$, $i = 1, 2, \ldots, N$ is the sample number. Our classifier design follows dimension reduction to get PCA feature vectors
and form the class scatter matrix $S_w$ and the within class scatter matrix $S_b$. Calculate the corresponding matrix $W_{LDA} = [\alpha_1, \alpha_2, ..., \alpha_l]$. Then we use the LDA transformation matrix $W_{LDA}$ as

$$z_i = [z_{i1}, z_{i2}, ..., z_{in}] = W_{LDA}^T e_i, \quad i = 1, 2, ..., N$$

Thus, we can use the best classification feature vector to replace the feature vectors for identification and classification.

### 3.2.6 Matching and recognition

Through the above wavelet decomposition and PCA transform for each sub-image $B_i$, we obtain wavelet moments $w_{22}$ and extract feature vector $z$ of PCA and LDA. $B_i$ is characterized by $v_i = [w_{22}; z]$. Matching feature vectors of finger 1 $v_1 = [w_{22}; z]$ and of finger 2 can be done as follows.

#### 3.2.6.1 Matching

The first step is the length of $V$ and $V'$ may not be the same, that is, $k$ and $k'$ is not necessarily the same. Here we define:

$$K = \min(k, k')$$

Taking the $K$ vectors of $V$ and $V'$ for comparison, first analyze the corresponding sub-image blocks $v_i$ and $v'_i$.

$$v_i = [w_{22}; z], \quad v'_i = [w'_{22}; z']$$

From several experiments, we set two threshold vectors $w_i$, $z_i$. Euclidean distance between $B_i$ sub-images, $\delta_i$ is defined for two feature vectors $w$ and $w'$ from $V$ and $V'$. A matching score defined for $V$ and $V'$ feature $w_{22}$ of wavelet moment of corresponding sub-image $B_i$ matching score:

$$w_{\text{mark}} = \begin{cases} \frac{w_i - \delta_i}{w_i} & \text{if } \delta_i < w_i \\ 0 & \text{else} \end{cases}$$

Finally, we obtain wavelet moment feature of the finger matching score:

$$w_{\text{mark}} = \sum_{i=0}^{K} w_{\text{mark}}$$

Similarly, we create a match $V$ and $V'$, of the feature vector $z$ scores $z_{\text{mark}}$.

Finally, combining the scores:

$$\text{total}_{\text{mark}} = s_1 \times w_{\text{mark}} + s_2 \times z_{\text{mark}}$$

$s_1, s_2$ are the share of feature matching scores, and $s_1 \geq 0, s_2 \geq 0, s_1 + s_2 = 1$. 

www.intechopen.com
Thus, if the finger vein 1 and 2 match total mark value score is greater than a given threshold, the two fingers match, otherwise they do not match. A minimum distance classifier can also be used for the recognition task.

4. Experimental results

4.1 Processing experimental results
To verify the effectiveness of the proposed method, we test the algorithm using images from a custom finger vein image database. The database includes five images each of 300 individuals’ finger veins. Each image size is 320*240.

Fig. 15. Experimental results

We have used a variety of traditional segmentation algorithms and their improved algorithms to segment vein image. But segmentation results of vein image by these algorithms aren’t ideal. Because the result of NiBlack segmentation method is better than other methods [13], we use NiBlack segmentation method as the benchmark for comparison. Segmentation was done for all the images in our database using NiBlack segmentation method and using our method. Experimental results show that our method has better performance. To take full account of the original image quality factor, we select two typical images from our database with one from high quality images and the other from poor quality images to show the results of comparative test. Where Fig. 15(a) is the high-quality vein image in which veins are clear and the background noise is small. Fig. 15(b) is the low-quality vein image. The uneven illumination caused the finger vein image to be fuzzy, which seriously affects image quality. We extract veins feature by using our method and compare with results of the NiBlack segmentation method. Experimental results shown in Fig. 15(c) and Fig. 15(e) are obtained from the NiBlack method applied in [9]. This algorithm extracts smooth and continuous vein features of high-quality image. There are a few pseudo-vein characteristics in Fig. 15(c). But in Fig. 15(e), there is much noise in the segmentation results. Segmented image features have poor continuity and smoothness, and there is the effect of the over-segmentation. Experimental results show that apart from smoothness and continuity or removal of noise and pseudo-vein characteristics, the method proposed in this paper extracts vein features effectively not only from the high-quality
images but also from the low-quality vein images as shown in Fig.15(d) and Fig.15(f). We show that the algorithm proposed in this paper performs better than the traditional NiBlack method.

4.2 Relative distance and angle experimental results
Finger-vein images (size 320×240) of 300 people were selected randomly from Harbin Engineering University finger-vein database. One forefinger vein image of each person was acquired, so there are 300 training images. Generally, a good recognition algorithm can be successfully trained on a small dataset to get the required parameters and achieve good performance on a large test dataset. Therefore four more images from the forefinger of those 300 people were acquired giving a total sum of 1200 images to be used as verification dataset.

When matching, every sample is matched with others, so there are (300×299)/2 = 44850 matching times; 300 of which are legal, while the others are illegal matches. Two different verifying curves are shown in Fig.16. The horizontal axis stands for the matching threshold, and vertical axis stands for the corresponding probability density. The solid curve is legal matching curve, while the dashed is illegal. Both curves are similar to the Gaussian distribution. The two curves intersect, at a threshold of 0.41. The mean legal matching distance corresponds to the wave crest near to 0.21 on the horizontal axis, and the mean of illegal matching distance corresponds to the wave crest near to 0.62 on the horizontal axis. The two wave crests are far from each other with very small intersection. So this method can recognize different finger-veins, especially when the threshold is in the range [0.09-0.38], where the GAR is highest.

Fig. 16. Legal matching curve and illegal matching curve

The relationship between FRR and FAR is shown in Fig.17. For this method, the closer the ROC curve is to the horizontal axis, the higher the Genuine Acceptance Rate (GAR). Besides, the threshold should be set suitably according to the fact, when FRR and FAR are equivalent, the threshold is 0.47, that is to say, EER is 13.5%. In this case, GAR of the system is 86.5%. The result indicates that this method is reasonable, giving accurate finger-vein recognition.

The method above compares the numbers of relative distances and angles which are approximately equivalent from two finger-vein images. In the second step, only the
intersecting points which are matched successfully on the first step are used and thus, computation of superfluous information is avoided and only information vital to decision making is used. Only when the two matching steps are successful is the recognition successful. According to Theorem 3, the relative distance and angle would not change even after image translation and rotation. So the proposed algorithm is an effective method for finger-vein recognition.

Fig. 17. ROC curve of the method

In 1:1 verifying mode, compare the one image out of 1200 samples in verifying set with the image, which has the same source with the former one, in training set to verify. The experiment result is shown in Tab.1, the times of success are 1120, and the rate of success is 93.33%. In 1:n recognition mode, compare the 1200 images with all images in training set, 360000 times in sum. The result is as Tab.2, the times of FAR is 25488, and GAR is 92.92%.

To test the ability to overcome image translation and rotation, translate randomly in the range \([-10, +10]\) and rotate the image randomly in the range \([-10^\circ, +10^\circ]\), in order to establish the translation and rotation test sets. Then verify and recognize the two sets respectively. The samples which have the same source are compared in a 1:1 experiment; matching each sample from the two sets with the samples from the training set to accomplish 1:n experiment. The result is shown in Tab.3, Tab.4, Tab.5 and Tab.6.
### 4.5.5 Experimental results analysis

The algorithm was implemented on a Windows XP platform using Visual C++ 6.0. Finger vein image capture was performed taking into account the convenience of users, while collecting index finger and middle finger vein images. A total of 287 finger vein images collected for each finger 5 times, and in all, a total of $287 \times 5 = 1435$ were collected to form finger vein library. Two sets $287 \times 2 = 574$ were taken for verification.

The identification results based on template matching:

We first according to the method proposed in reference [1], recognition for the veins of our library of images. In 1:1 verification mode, we use the validation library of 574 samples to verify the experimental results shown in Tab.7.

Table 4. Translation test set recognition result (1:n)

As the experiment shows, in 1:1 mode the rate of success can reach 92.58% even though the finger-vein image is translated, and can reach 91.75% when rotated. In 1: n mode, GAR can reach 92.25% and 91.17% respectively, which implies a robust recognition system. Further, the method can overcome the influence caused by image translation and rotation, thus it can meet practical requirements.

</tr>
</tbody>
</table>
As seen from the recognition results, recognition rate and rejection rate in the method based on wavelet PCA can meet the requirements of practical applications. In recognition speed, that is, 1: n of the mode can meet the requirements.

5. Conclusion

Accurate extraction of finger vein pattern is a fundamental step in developing finger vein based biometric authentication systems. Finger veins have textured patterns, and the directional map of a finger vein image represents an intrinsic nature of the image. The finger vein pattern extraction method using oriented filtering technology. Our method extends traditional image segmentation methods, by extracting vein object from the oriented filter enhanced image. Experimental results indicate that our method is a better enhancement over the traditional NiBlack method [11], [12], [13], and has good segmentation results even with low-quality images. The addition of oriented filter operation, extracts smooth and continuous vein features not only from high quality vein images but also handles noisy low quality images and does not suffer from the over-segmentation problem. However, it requires a little more processing time because of the added oriented filter operation. Topology is an essential image property and usually, even an inflection point may contain plenty of accurate information. Finger-vein recognition is faced with some basic challenges, like positioning, the influence of image translation and rotation etc. To address these problems, essential topology attributes of individual finger veins are utilized in a novel method. Particularly, the relative distance and angles of vein intersection points are used to characterize a finger-vein for recognition, since the topology of finger-vein is invariant to image translation and rotation. The first step is to extract those intersecting points of the thinned finger-vein image, and connect them with line segments. Then relative distances and angles are calculated. Finally combine the two features for matching and recognition. Experimental results indicate that the method can accurately recognize finger-vein, and to a certain degree, overcome the influence image translation and rotation. Furthermore, the method resolves the difficult problem of finger-vein positioning. It is also computationally efficient with minimal storage requirement, which makes the method of practical significance. However there are still problems of non-recognition and false recognition. Besides, pre-procession is an import requirement for this method and the accuracy of pre-processing influences recognition result significantly. In view of this, further research will be done on the pre-procession method, to improve the image quality and the accuracy of feature extraction, and subsequently improve system reliability.

This chapter discussed recent approaches to solving the problem of varying finger lengths and proposed using a set of images of same size interval in a selected sub-block approach. For each image sub-block, wavelet moment was performed and PCA features extracted. LDA transform is performed, and the two features were combined for recognition. For

matching and identification, we proposed a method of fuzzy matching scores. Experimental results show that wavelet moment PCA fusion method achieved good recognition performance; error rate FAR was 0.7%, rejection rate FRR of 1.05%. In future research, we are committed to further study finger vein feature fusion with fingerprint and other features to improve system reliability.

[16] Xueyan Li. Study of Multibiometrics System Based on Fingerprint and Finger Vein[D]. the doctorate dissertations of Jilin University. 2008.

Biometrics uses methods for unique recognition of humans based upon one or more intrinsic physical or behavioral traits. In computer science, particularly, biometrics is used as a form of identity access management and access control. It is also used to identify individuals in groups that are under surveillance. The book consists of 13 chapters, each focusing on a certain aspect of the problem. The book chapters are divided into three sections: physical biometrics, behavioral biometrics and medical biometrics. The key objective of the book is to provide comprehensive reference and text on human authentication and people identity verification from both physiological, behavioural and other points of view. It aims to publish new insights into current innovations in computer systems and technology for biometrics development and its applications. The book was reviewed by the editor Dr. Jucheng Yang, and many of the guest editors, such as Dr. Girija Chetty, Dr. Norman Poh, Dr. Loris Nanni, Dr. Jianjiang Feng, Dr. Dongsun Park, Dr. Sook Yoon and so on, who also made a significant contribution to the book.
