Sinterability and Dielectric Properties of ZnNb$_2$O$_6$ – Glass Ceramic Composites

Manoj Raama Varma, C. P. Reshmi and P. Neenu Lekshmi

Materials and Minerals Division,
National Institute for Interdisciplinary Science and Technology [NIIST], Thiruvananthapuram, India

1. Introduction

In the new era of communication technology there are revolutionary developments in satellite communication, global positioning systems and mobile communication systems, which has helped the developments in multilayer technologies like low temperature cofired ceramics (LTCC). The microwave electronic devices have achieved significant miniaturisation, light weight and became very cost effective using LTCC. The characteristic properties required for dielectric materials which are used in multilayers are (a) high dielectric permittivity ($\varepsilon_r$), (b) high quality factor (Q×f) and (c) low temperature coefficient of resonant frequency ($\tau_f$). The size of the resonator is inversely related to the $\sqrt{\varepsilon_r}$. Dielectric materials should possess near zero temperature coefficient of resonant frequency ($\tau_f$) for thermally stable electronic devices [1-7].

Generally most of the dielectric ceramic materials are known to possess the above said properties but will sinter at temperatures above 1000 °C. Zinc niobates, ZnNb$_2$O$_6$ (ZN) is a low loss dielectric material with columbite structure having excellent dielectric permittivity, high quality factor and low temperature coefficient of resonant frequency. Sintering temperature of ZN is comparatively lower (~1200 °C) [8]. Hence it is widely used as dielectric resonators in microwave communication devices. In multilayer ceramic structures, the low melting electrodes such as Ag (melting point ~961 °C), Cu (melting point ~1083 °C) and Au (melting point ~1064 °C) are co-fired with these ceramic materials [9,10]. In the case of Ag electrodes, processing temperature of the material must be below 950 °C.

There are several approaches to reduce the sintering temperature of the ceramics viz. (i) usage of ultra-fine particles/powders as synthesized by wet chemical methods as starting materials (ii) addition of low melting glasses to obtain a low temperature sintering composite [11-14]. Glass addition is known to be the most popular and least expensive method and hence ZN is widely used in ceramic technology.

Even though the ZN ceramics prepared by conventional ceramic route [1-6] shows excellent properties, high sintering temperature preclude its application potential in the LTCC. Usage of nano sized ZN powders (instead of micron size powders) in multi layer technology can bring down the sintering temperature to a lower value. Hence the procedure for preparing...
ZN ceramic powder as both micron size powders and nanosized powders and the sinterability of pure materials as well as the glass added ceramics are described in this chapter. The structural characterisation of the materials can be done using XRD and the microwave dielectric properties (in the frequency range 2-6 GHz) can be studied and compared to highlight the effect of particle size on sinterability and microwave dielectric properties of these materials.

2. Materials and methodologies

ZN ceramic powders can be synthesized using two different well established preparation techniques such as solid state ceramic method and polymer complex techniques [15-17].

2.1 Synthesis of ZnNb$_2$O$_6$ using solid state synthesis technique

Single phase ZN can be prepared using oxides of Zn (ZnO 99.9+%) and pentoxide of Niobium (Nb$_2$O$_5$ 99.9+%) as raw materials. These oxides can be weighed in stoichiometric proportion and mixed for 24h in a ball mill, using zirconia balls and distilled water as the milling medium. The slurry can be dried at 80°C and the dried powder can be calcined at 850°C/4h, to get the phase pure ZN ceramics.

2.2 Preparation of ZnNb$_2$O$_6$ using polymer complex method

Zinc acetate [Zn(CH$_3$COO)$_2$ 99.99%] and niobium ethoxide [Nb(OC$_2$H$_5$)$_5$ 99.95% metal basis] can be used as the starting material for preparing ZN using polymer complex method. The flow chart, in Fig. 1 shows the various steps involved in the synthesis. 3 mol equivalent of citric acid can be dissolved in 12 mol of ethylene glycol with continuous stirring for 1h to form a clear solution. 1 mol of zinc acetate can then be added and stirred for several hours at 80°C to dissolve it completely. 2 mol of Nb(OC$_2$H$_5$)$_5$ can be added to this clear solution with a stirring speed of 500 rpm until it results in the formation of a thick white gel. The gel can be sonicated for 2h to obtain the uniform distribution. After sonication the polymeric precursor can be recovered by desalting with acetone. The dried polymeric precursor can be calcined at 600°C/4h to obtain the ZnNb$_2$O$_6$ nanopowders.

2.3 Preparation of 60ZnO-30B$_2$O$_3$-10SiO$_2$ (ZBS) glass

High purity ZnO, B$_2$O$_3$ and SiO$_2$ (99.9%) can be used as the raw materials for the preparation of 60ZnO-30B$_2$O$_3$-10SiO$_2$ (ZBS, sintering temperature is <800°C). The raw materials weighed accurately in the stoichiometric proportion are mixed well in distilled water medium using zirconia balls for 24 h in a ball mill. The slurry can be dried and the powder can be melted in a platinum crucible at 1000°C for 2h, and the melt can be quenched into cold distilled water and powdered. This glass powder can be used for the preparation of glass ceramic composites.

2.4 Preparation of ZN-ZBS glass composites

Appropriate amounts of ZN and ZBS glass (1,3,5,10 wt%) can be mixed using an agate mortar for 2 hours in distilled water medium and the slurry can be dried and powdered. 3wt% PVA solution can then be added to this mixture as a binder. The dried powder can be uniaxially pressed using a tungsten carbide (WC) die in the form of cylindrical discs of
Fig. 1. Flow chart for the preparation of ZnNb₂O₆ nano powders
diameter 14 mm and about 7 mm height at a pressure of 150 MPa. The green compact can be heat treated at different temperatures and the dimension changes are recorded. The density can be determined each time and the sintering temperature can be optimised as the temperature which gives the maximum densification.

The sintered pellets of all the compositions can be powdered and the crystalline phase of the powders are identified by the XRD analysis using Cu-Kα radiation of wavelength (λ) 1.54056Å for 2θ range 10-80°. The recorded patterns are compared with standard ICDD Data file with the help of Philips X’pert High Score plus software. The ZN nano particles can be characterised using transmission electron microscopy (HRTEM) FEI Technai G² 30S-TWIN high resolution electron microscope operated at 300 KV. The crystallite size, lattice parameter and the selected area diffraction patterns can be recorded using TEM. The crystallite size (d) of the nano-ZN was determined from the XRD patterns using Debye Sherrer formula [18,19],

\[
d = \frac{0.9\lambda}{\beta \cos\theta}
\]  

where \(\lambda\) is the wavelength of the x-ray, \(\beta\) is the FWHM of the maximum intense peak and \(\theta\) is the glancing angle.

The microstructure analysis of the sintered polished and thermally etched samples can be carried out using scanning electron microscope (SEM, JEOL-JSM, 5600LV, Tokyo, Japan). The bulk densities of the sintered pellets can be measured by the Archimedes method. The dielectric constant can be measured using the post resonator method of Hakki and Coleman modified by Courtney. The unloaded quality factor can be measured by a resonant copper cavity whose interiors are coated silver and the ceramic composites are placed on a low loss quartz spacer which reduces the effect of losses due to surface resistance of the cavity using a Vector Network Analyser. The temperature coefficient of resonant frequency (\(\tau_f\)) can be measured by noting the temperature variation of the same using TE\(_{01}\delta\) mode in the transmission configuration over a range of temperature 20-80°C. The temperature coefficient of the resonant frequency can be calculated using the following relation in a fixed interval of temperature [20-22],

\[
\tau_f = \frac{f_2 - f_1}{f_1 (T_2 - T_1)}
\]  

where, \(f_1\) and \(f_2\) are the resonant frequencies at temperatures \(T_1\) and \(T_2\) respectively and the average value can be calculated and reported.

3. Observations and analysis

Fig 2(a) is the powder XRD diffraction pattern of ZnNb\(_2\)O\(_6\) synthesized using solid state ceramic route. All the peaks are compared with the ICDD file card for ZN (Number 76-1827) and indexed. Fig 2 (b) depicts the XRD pattern of ZnNb\(_2\)O\(_6\) with 5wt% of zinc borosilicate glass (ZBS). The addition of ZBS glass did not produce any additional phases, as evident from Fig. 2 (b).
The powder XRD patterns of the calcined ZnNb$_2$O$_6$ nanopowders are depicted in the fig 3. Fig 3(a) shows the XRD pattern of ZnNb$_2$O$_6$ calcined at 600 °C/4h and fig 3 (b) is that of ZnNb$_2$O$_6$ powder sintered at 950 °C/2h. The figures clearly indicate that the powder patterns are in well accordance with ICDD data card (76-1827). The average crystallite size of the nanostructured ZN calcined at 600 °C/4h can be estimated from the X-ray diffraction pattern. The fig 4 depicts the maximum intense peak obtained from XRD of ZN ceramics. Using Gaussian fit (as seen in the fig 4), the FWHM and centre of the peak can be determined. Employing Debye Sherrer formula (equation 1) the average crystallite size can be calculated as ~17 nm.
Fig. 3. XRD pattern of ZnNb$_2$O$_6$ (a) calcined at 600°C/4h and (b) calcined at 950°C/2h.

Fig. 4. Maximum intense peak in XRD pattern of nanostructured ZN ceramics with theoretical Gaussian Fit.
Fig 4 shows the various TEM images of ZN nanocrystallites. Fig 5 (a), (b) and (c) are the TEM images of the ZN nanocrystallites at two different regions. It can be seen that in both images the nanocrystallites have same characteristics and mostly of spherical in shape. The fig 5 (c) establishes the crystallite size at low magnification; they are well separated and have uniform size distribution. A histogram is shown in fig 5 (d), indicates the crystallite size obtained from the images both fig 5 (a) and (b). In order to obtain particle size distribution, a Gaussian function is fitted for the experimental data. The average particle size is obtained and found that it is lies between 18-20 nm. This is in good agreement with the crystallite size obtained from XRD using Debye Scherrer formula.

Fig 5. TEM images of nano ZnNb$_2$O$_6$ (a), (b) 50 nm scale, (c) 100 nm scale and (d) histogram of particle size distribution obtained from image (a) and (b).
The high resolution TEM (HRTEM) image and the selected area diffraction pattern (SADP) of ZN nanocrystallites are shown in the fig 6 (a) and (b) respectively. Lattice plane of ZN nanoparticles are clearly visible in the HRTEM image. Interplanar spacing ‘d’ of several planes were determined using set of Fourier Transforms of lattice fringe images. TEM image analysis software (Digital Micrograph - Gatan) was used for the determination of interplanar spacing. The average d values were determined and the plane corresponding to each set of fringes are duly indexed, shown in the fig 6 (a). Interplanar spacing obtained from TEM and XRD are tabulated in table 2. Comparing the d values from the X-ray diffraction pattern, the planes corresponding to each ring was identified and indexed.

Fig. 6. (a) HRTEM of nanostructured ZN ceramic (b) SAD patterns of ZN ceramics.

In fig 7, variation of bulk density of pellets, synthesised by solid state ceramic route and heat treated at 975°C with different wt% of ZBS is shown. From the fig 7, ZN ceramics with 5 wt% of ZBS has maximum density. Hence 5 wt% of ZBS is taken as the optimized glass addition amount for the composite. Fig 8 illustrates the variation of the bulk density of ZN and ZN-ZBS glass composites with varying sintering temperatures. From Fig. 8 it can be seen that nanostructured ZN with 5 wt% of ZBS glass has greater density at lower sintering temperatures (925°C/2h). Comparison of densification of pure (nano and micron sized) ZN ceramics shows that the densification is faster for nano powder compacts at lower temperatures, however at temperature above 1100°C for micron sized powder compacts synthesised by solid state ceramic route has higher absolute density. Since the nano powders of ZN have higher sinterability, the growth during the sintering process will be more rapid. Hence more finer intergranular porosities will be formed in the case of nano powder compacts than micron sized powder compacts. This will results in the reduction in the values of absolute densities of sintered powder compacts. Similar effects were noticed for sintered nano sized powder compacts of BZT by Manoj Raama Varma et al. [23] In nanostructured ZN ceramics the grain boundary area per unit volume will be more than that of the solid state synthesised ZN ceramics [24]. This deteriorates the densification of
Fig. 7. Variation of bulk density of ZN ceramics (solid state synthesis) with different wt% of ZBS glass

Fig. 8. Variation of the bulk density of ZN ceramics and ZN-glass composites with different temperature
nano sized ZN ceramics. In the case of glass addition, low melting glasses such as ZBS enhances the sinterability of the ZN ceramic powders due to the liquid phase sintering [25,26]. The glasses start melting at lower temperatures and the molten glasses flows through the porosity between the grains and fill the porosity and the gap between the grain Boundaries [27]. This enhances the sinterability i.e. the composite gets densified at lower sintering temperatures. Hence the ZN composite with 5 wt% ZBS glass shows higher density than that of the pure materials. The effect of liquid phase sintering is clearly seen in the SEM micrographs (Fig. 9) as molten glass melted at low temperatures.

Fig. 9 shows the SEM micrographs of the sintered ZN. Fig. 9 (a) and (b) are SEM micrographs of ZN synthesised using solid state ceramic route. Large grains having average grain diameter of ~4.2 µm were observed for pure ZN. Though the sintering has taken place, Fig. 9 (b) shows a highly densified microstructure with large amount of molten glass phases for glass-ZN composites. It is observed that by the addition of ZBS glass the grain growth decreases. In fig 9 (b) the grains have an average diameter of about 1 to 2 µm only. Fig 9 (c) shows the SEM images of the sintered nano structured ZN (obtained via chemical synthesis) which are sintered at 925 °C for 2h. The SEM micrograph exhibits highly dense grains. Average grain size obtained from the micrograph images ranging from about 1-2 µm. It reveals fine sintered grains are obtained by sintering of nano ZN powder. Fig 9 (d) shows micro structure of the nanostructured ZN ceramic powders with 5wt% of ZBS glass. Comparatively smaller grains are obtained for the glass added nano powder compacts of ZN. The densification is very high for a much lower sintering temperature viz 925°C/2hrs.
Comparing all images in Fig. 9 the nanostructured ZN with 5wt% of ZBS shows very high packing with a minimum porosity at 925 °C/2h. The density and the dielectric properties viz dielectric constant $\varepsilon_r$, $Q\times f$, and $\tau_f$ of ZN ceramics are tabulated in table 2. Comparison of these properties of the materials synthesised by different preparation techniques reveals that the solid state synthesised shows greater values for dielectric constant and $Q\times f$. This can be correlated with the effect of grain size. In ceramic materials the increase in the grain size deteriorates the dielectric loss. Reduction in the number of grains per unit volume, decreases of grain boundaries per unit volume and it would result in a material with a lower dielectric loss and better polarisability which improves both $\varepsilon_r$ and $Q\times f$ [28,29]. From the SEM micrographs (Fig. 9) it can be concluded that the nanostructured ZN has more grain boundaries than solid state synthesised ZN and hence had a low $\varepsilon_r$ and $Q\times f$. However the glass addition to these compounds, due to liquid phase sintering the nanostructured ZN has greater densification at lower sintering temperature. The dielectric properties of micron sized ZN ceramic with 5 wt% of ZBS are: density = 5.48, $\varepsilon_r$ = 21.3, $\tau_f$ = -66 ppm/°C and with $Q\times f$ ~38,000, sintered at 975 °C/2h. Dielectric properties of sintered nano sized ZN with 5 wt% of ZBS have density = 5.21, $\varepsilon_r$ = 22.5, $\tau_f$ = -69.6 ppm/°C and with $Q\times f$ ~12,800, sintered at 925 °C/2h [30]. Since ZnNb$_2$O$_6$+5wt%ZBS can be identified as one of the potential LTCC materials sintering at 925°C, co sintering studies were done with silver. ZnNb$_2$O$_6$+5wt%ZBS was mixed with 20wt% metallic Ag (99.99%) and sintered at 930°C/2h. SEM pictures with EDAX was recorded after sintering and found that Ag is not reacting or melting during the sintering. Hence the co sintering of ZnNb$_2$O$_6$+5wt%ZBS+20wt%Ag was successful as can be seen in fig.10.

4. Conclusions

Zinc Niobates ceramics were prepared in phase pure powder form using solid state ceramic technique and polymer complex method. Particle size of the ZN ceramics is determined using TEM and it is found most of the particles are in the range 18-20 nm, the particle size obtained from XRD pattern using Debye Sherrer formula is 17 nm. Effect of particle size on the sinterability and the microwave dielectric properties were studied. Micro structure shows that a high density ZN ceramics can be obtained by sintering nanopowder of ZN with 5wt% of ZBS glass at 925 °C for 2h. Optimized sintering of nano sized powder at 925 °C/2h give microwave dielectric properties of $\varepsilon_r = 22.5$, $Q\times f \sim 12,800$ and $\tau_f = -69.6$ ppm/°C. These composites were successfully co sintered with silver.

Sinterability studies and microwave dielectric properties of sol–gel synthesized Ba(Zn$_{1/3}$Ta$_{2/3}$)O$_3$ nanoparticles, Manoj Raama Varma, P. Nisha and P.C. Rajath Varma, Journal of Alloys and Compounds, 457, 2008,422-428

The current book contains twenty-two chapters and is divided into three sections. Section I consists of nine chapters which discuss synthesis through innovative as well as modified conventional techniques of certain advanced ceramics (e.g. target materials, high strength porous ceramics, optical and thermo-luminescent ceramics, ceramic powders and fibers) and their characterization using a combination of well known and advanced techniques. Section II is also composed of nine chapters, which are dealing with the aqueous processing of nitride ceramics, the shape and size optimization of ceramic components through design methodologies and manufacturing technologies, the sinterability and properties of ZnNb oxide ceramics, the grinding optimization, the redox behaviour of ceria based and related materials, the alloy reinforcement by ceramic particles addition, the sintering study through dihedral surface angle using AFM and the surface modification and properties induced by a laser beam in pressings of ceramic powders. Section III includes four chapters which are dealing with the deposition of ceramic powders for oxide fuel cells preparation, the perovskite type ceramics for solid fuel cells, the ceramics for laser applications and fabrication and the characterization and modeling of protonic ceramics.
