Genetic Modification of Domestic Animals for Agriculture and Biomedical Applications

Cai-Xia Yang and Jason W. Ross
Department of Animal Science, Iowa State University, USA

1. Introduction

Transgenic technology has been applied mainly in the study of gene structure and function in model organisms and gene therapy for human diseases. Transgenic technology has potential for rapidly improving quantity and quality of agricultural products, compared to traditional selection and breeding methods in domestic animals that are time consuming when attempting to alter the desired allele frequency for specific traits. Additionally, transgenic animals can be used as biomedical research models or directly for human health, by producing recombinant pharmaceutical proteins and/or organs for xenotransplantation. Due to the advantage of bypassing the need of embryonic stem (ES) cells that are difficult to isolate in domestic animal species, cell-based method of transgenesis followed by somatic cell nuclear transfer (SCNT) is currently widely applied. However, due to the limitations in making genetic modifications and SCNT, producing genetically modified animals is still inefficient. Fortunately, the current advancement of new techniques and methods in both gene targeting (Urnov et al., 2010) and abilities to produce pluripotent stem cells (Voigt and Serikawa, 2009) holds great promises for this field.

In this chapter, we will review the recent progress and technical route of the cell-based method of transgenesis by SCNT and discuss the newly emerging methods to enrich the gene targeting frequency of somatic cells. We will also discuss factors to improve the efficiency of SCNT and our future perspectives on the promises of this field.

2. Recent progress and applications of transgenic domestic animals

2.1 Methods of creating genetically modified animals

2.1.1 Pronuclear microinjection /viral-mediated /sperm-mediated /ICSI (Intractyoplasmic sperm injection)- mediated gene transfer

Numerous methods have been successfully used to introduce genetic modifications and produce transgenic animals, including pronuclear microinjection of foreign DNA into zygotes (Hammer et al., 1985; Pursel and Rexroad, 1993), viral-mediated gene transfer (Chan et al., 1998; Cabot et al., 2001; Whitelaw et al., 2008), sperm-mediated gene transfer (Castro et al., 1991; Chang et al., 2002; Lavitrano et al., 2002 and 2006) and intracytoplasmic injection (ICSI) of a sperm head carrying foreign DNA (Perry et al., 1999; Osada et al., 2005; Moisvadi et al., 2009; García-Vázquez et al., 2010). Despite the proven successful application of these techniques, some problems, such as inefficiency and mosaicism (transgene not going into the germline) (Table 1) remain to be solved and limit the practical application of these methods.
## Table 1. The Advantages and disadvantages of different transgenic methods.

</thead>
<tbody>
<tr>
<td>Pronuclear microinjection</td>
<td>The first method successfully used for different animal species.</td>
<td>Low embryo survival, low and random integration, multiple copies, high cost in domestic animals.</td>
</tr>
<tr>
<td>Viral-mediated DNA transfer</td>
<td>Infect both dividing and non-dividing cells, less damage by co-culture with zona-free zygotes or injection into the perivitelline space compared with pronuclear microinjection, high integration.</td>
<td>Limited DNA capacity, random integration.</td>
</tr>
<tr>
<td>Sperm-mediated DNA transfer</td>
<td>Relatively high efficiency as compared to pronuclear injection, low cost, ease of use.</td>
<td>No control of integration site.</td>
</tr>
<tr>
<td>Intracytoplasmic sperm injection-mediated DNA transfer</td>
<td>Allow introduction of very large DNA transgenes, relatively high efficiency as compared to pronuclear injection.</td>
<td>No control of integration site.</td>
</tr>
</tbody>
</table>
Gene targeting by homologous recombination often offers more precise and site-specific integration, sometimes at single nucleotide level. This is particularly important since single nucleotide changes can be a common culprit for some of the human diseases, which require more precise manipulation to build biomedical models using transgenic animals.

2.1.2 Cell-based transgenesis via SCNT
The first live animal by SCNT was produced in 1997, “Dolly” (Wilmut et al., 1997), demonstrating the ability of a differentiated somatic cell to produce live offspring following nuclear remodeling and reprogramming by an oocyte. Then, the birth of “Polly” in the same year (Schnieke et al., 1997), the first transgenic sheep produced by transfer of nuclei from transected fetal fibroblasts, demonstrated a route to create transgenic cloned animals. This cell-based method of transgenesis by SCNT can bypass the absence of ES cells, offers the reliability of germline transmission by avoiding mosaic transgene integration, and provides the only currently used strategy to knock out a gene in domestic animals (reviewed by Ross et al., 2009a). Currently, SCNT using transgenic cells cultured in vitro as a source of donor nuclei is becoming the most utilized technique to produce the transgenic domestic animals. However, while the advantages and success of this strategy are well documented (Table 2), the procedure is still labor-intensive and inefficient. Recently, some new techniques have been reported that may have the potential to improve the production efficiency of cloned transgenic domestic animals by increasing the efficiency of gene targeting or nuclear remodeling and reprogramming following SCNT.

2.2 Utilization of transgenic models
The potential for transgenic domestic animals to benefit humans is not only in agricultural production by providing more and better agricultural products for human consumption but also in biomedicine, such as for producing recombinant pharmaceutical proteins, making organs suitable for xenotransplantation and establishing human disease models. An overview list of the transgenic domestic animals produced via SCNT is given in Table 2 to demonstrate their applications.

2.2.1 Improved animal agriculture production
Increased utilization of domestic animals and their products requires breeding and selection strategies for specific traits. However, classical breeding and genetic selection have some disadvantages, such as the inability to control gene frequency of desired genotypes coupled with long generation intervals. The application of transgenic technology offers a powerful tool to rapidly improve agriculture product by developing domestic animals that express desired traits via genome manipulation strategies. Previous studies have demonstrated the practical application of transgenesis to improve numerous agricultural traits of domestic animals, including increased growth rate (Purse et al., 1999), increased meat quality (Saeki et al., 2004), enhanced disease resistance (Lo et al., 1991; Clements et al., 1994), and better milk production and composition (Wheeler et al., 2001; Reh et al., 2004). Nevertheless, utilization of the cell-based method of transgenesis via SCNT has also been successfully used to alter characteristics of pork quality (Lai et al., 2006), enhance disease resistance (Denning et al., 2001a; Wall et al., 2005; Richt et al., 2007) and improve milk composition (Brophy et al., 2003).

2.2.2 Xenotransplantation

Due to the potential application of human organ transplantation and the growing gap between the demand and availability of organs for transplantation, the pig has long been considered as an alternative source to provide organs for humans. In contrast to organs from other animal species, domestic pig organs share many similarities to those of humans including size, anatomy and physiology. However, despite these similarities, significant immunological barriers exist impeding the success of pig to human xenotransplantation (Cooper et al., 2008), in addition to concerns regarding the transmission of pig specific viruses to the human genome (Magre et al., 2003). The immunological obstacles of xenotransplantation include rapid hyperacute rejection (HAR), delayed acute vascular rejection (AVR), and the cellular immune response that occurs within weeks (Auchincloss and Sachs, 1998). Two transgenic strategies have been successfully applied to overcome HAR. One is to express human proteins that inhibit the complement cascade in transgenic pigs (Fodor et al., 1994; Cozzi and White, 1995; Diamond et al., 2001). For example, transgenic expression of human complement inhibitor CD59, CD46 and DAF (decay-accelerating factor, also named as CD55) in pigs prolongs survival rates from minutes to days and months following heart and kidney transplantation into baboons or monkeys by blocking the damage from HAR (Diamond et al., 1996 and 2001; Byrne et al., 1997; Zaidi et al., 1998; Bhatti et al., 1998; Chen et al., 1999).

The second strategy to avoid HAR is to knockout the genes that induce the production of antigenic structures (α-gal-epitopes) on the surface of pig organs (Lai et al., 2002a; Dai et al., 2002; Phelps et al., 2003; Yamada et al., 2005). α-gal-epitopes on endothelial cells of porcine transplanted organs can be recognized by human xenoreactive natural antibodies (XNA) and activate the HAR cascade (Galili, 1993). Genetically engineering of pigs to lower or inhibit the expression level of XNA targets is thought to be a promise way to eliminate the HAR. Following the successful production of α-1,3-galactosyltransferase knockout pigs (Lai et al., 2002a; Dai et al., 2002; Phelps et al., 2003; Yamada et al., 2005), van Poll et al. (2010) recently showed that exposure of isolated xenogenic pig liver sinusoidal endothelial cells (LSECs) from α-1,3-galactosyltransferase-deficient pigs to human and baboon serum reduces IgM binding and complement activation levels as compared to wild-type pig LSECs. However, Diswall et al. (2010) found a different reactivity pattern of baboon and human serum to pig glycolipid antigens isolated from α-1,3-galactosyltransferase knockout and wild-type pig hearts and kidneys, suggesting that non-human primates may not be an ideal model for modeling pig to human xenotransplantation. If HAR is controlled, the next obstacle to xenotransplantation is AVR which is due to the loss of porcine thrombomodulin in xenograft rejection or the inability of porcine thrombomodulin to activate human protein C. One of genetic engineering strategies to overcome AVR is to express human thrombomodulin in pigs. Petersen et al. (2006) showed the production of transgenic cloned pigs using CD59/DAF and human thrombomodulin triple transgenic adult donor cells.

With regard to risks associated with xenotransplantation, previous studies have shown that the risk of cross-transmission of pig endogenous retrovirus (PERV) to human patients or nonhuman primate recipients is low (Paradis et al., 1999; Switzer et al., 2001), although it has been found PERV can infect human cells in culture (Patience et al., 1997). Never-the-less, some investigators have been working to further reduce the possibility by creating
pigs with suppressed expression of endogenous retroviruses (Ramsoondar et al., 2009). In addition to PERV, herpesvirus is another concern regarding biosafety in xenotransplantation (Mueller et al., 2011). Overall, dramatically increased knowledge will facilitate the clinical application of transgenic strategies of pig to human xenotransplantation.

2.2.3 Production of recombinant proteins
The mammary gland and blood of transgenic domestic animals, including sheep, goats, cows, pigs and rabbits, have been successfully used as bioreactor to produce numerous recombinant proteins, such as antibodies (Grosse-Hovest et al., 2004), growth factors (Schnieke et al., 1997) and pharmaceuticals (reviewed by Melo et al., 2007). Using various mammary gland-specific or blood-specific promoters to drive the expression of specific protein-coding genes, transgenic domestic animals can continuously produce the recombinant proteins in large quantities in their milk or blood. Recombinant proteins, including human von Willebrand factor (Lee et al., 2009), human erythropoietin (Park et al., 2006), human insulin-like growth factor-I (Monaco et al., 2005), human factor VIII (Paleyanda et al., 1997) and bovine alpha-lactalbumin (Bleck et al., 1998) have been produced in the milk of transgenic pigs. Transgenic goats, capable of synthesizing human butyrylcholinesterase (Huang et al., 2007) and human longer acting tissue plasminogen activator (Ebert et al., 1991) in their milk have also been created. Human salmon calcitonin in milk of transgenic rabbits (McKee et al., 1998); human factor IX (Schnieke et al., 1997) and alpha-1-antitrypsin (Wright et al., 1991) in milk of transgenic sheep; and human alpha-1-antitrypsin (Wright et al., 1991) in milk of transgenic cows are all additional examples of using transgenic domestic animals and the mammary gland as a bioreactor for production of recombinant proteins. Table 2 summarizes some recombinant proteins expressed in milk or blood of cloned transgenic domestic animals. One of the major advantages of using domestic animals for this purpose is that the produced protein is thought to undergo more accurate posttranslational processing to ensure their biological activity. While this application of transgenic technology to produce recombinant protein products is rapidly developing, research efforts exploring the efficacy of these products are still needed.

2.2.4 Biomedical models of human diseases
Another important application of genetically modified domestic animals is to create better and novel biomedical models of human diseases. Pig models of different human diseases, including retinitis pigmentosa, cardiovascular disease, diabetes, Huntington’s disease, cystic fibrosis and Alzheimer’s disease have been well discussed by Prather et al. (2008). Many of these biomedical models created by SCNT are listed in Table 2.

3. Technical aspects of cell-based transgenesis by SCNT
The general procedure of cell-based transgenesis via SCNT is to construct a DNA vector, deliver the vector into cultured somatic cells, select transgenic cell lines, utilize SCNT and transfer cloned embryo into surrogates (Figure 1).
3.1 Vector construction

Currently, the whole genome sequence of several domestic animals, including cattle, poultry, cats, dogs, horses, pigs and rabbits is available via the ensembl database (www.ensembl.org), providing researchers useful sequence information for a large number of genes useful in designing DNA constructs for transgenic genome modification. Precise design and construction of DNA constructs is critical efficiently creating transgenic domestic animals. Transgenesis involves adding a gene to a host genome (transgenic), physically deleting a specific region of the host genome making a non-functional gene (knock-out), replacing an active gene by another active gene (knock-in), or introducing a point mutation (point mutation knock-in). Depending on the objective of the transgenic modification, different strategies of vector design need to be carefully considered to ensure success.

3.1.1 Transgenic vs. Knock-out vs. Knock-in

The design strategy for the transgenic vector, which is based on random integration, essentially includes a gene ORF (open reading frame), a promoter element and the appropriate RNA processing component(s). The promoter is a major transcriptional regulatory element that normally includes regulatory elements and the transcriptional start site typically located in 5' sequence of the gene. Utilization of specific promoter with a transgene enables tissue or cell specific expression and can significantly impact the expression efficiency of the transgene. Carefully choosing a well-characterized promoter

www.intechopen.com
will enable the precise control of transgene expression. The gene ORF is usually derived from the cDNA for the protein of interest, which includes translational start (ATG) and stop codons. Examination of extra sequence, if any, existing between the transcriptional start site and the translational start codon should be performed to ensure the absent of potential regulatory elements. Furthermore, consideration should be given to remove non-coding sequence of genes to avoid the introduction of the regulatory elements although this may also have consequences impacting mRNA stability. Reliable transgene expression is not only regulated by the sequence in the expression vector, but also by intrinsic factors in the host genome following transgene integration. Several additional points should be considered in transgenic vector construction. (i) How GC rich regulatory sequence are, especially CpG islands in the promoters can have significant implications for the expression of the transgene as methylation of CpG islands can inactivate the promoter and silence the transgene expression. (ii) Inclusion of specific elements that favor mRNA maturation and transfer to the cytoplasm, as it has been demonstrated that the inclusion of an intron in the transgenic vector can increase the transgene expression level (Choi et al., 1991; Duncker et al., 1997). These genomic regions may have critical sequence motifs affecting mRNA splicing and accumulation. (iii) Removal of unnecessary plasmid DNA sequence used in recombinant DNA cloning. In mice, it was found that plasmid sequence existing in the transgenic vector can decrease transgene expression (Kjer-Nielsen et al., 1992). Furthermore, the local chromatin status of the transgenic locus can also affect expression meaning that the integration of the same transgene in different genomic locations can have profound effects on the expression level of the transgene.

The primary strategy for targeted genome modifications, including knock-out and knock-in applications, is to use homologous recombination to introduce precise, site-specific genome alterations. In knock-out targeting vector systems, the primary approach is to delete DNA fragments (entire gene or partial deletion) important for the gene function by homologous recombination. Compared with the knock-out targeting vector, in addition to the targeting arms and positive selection cassette, the knock-in targeting vector includes the extra replacement cassette that will replace the target gene with a new gene (a set of genes or a point mutation). Targeting vectors relying on homologous recombination contain 5′ and 3′ homologous arms flanking a positive selection cassette (Rogers et al., 2008; Sun et al., 2008). Several principles should be considered when designing a successful targeting vector. (i) Avoid excessive repetitive DNA. In mouse ES cells it has been demonstrated that the excessive repetitive DNA within the targeting vector can significantly reduce targeting frequency (Wu et al., 2008). (ii) Use isogenic DNA as the source for producing exogenous homologous arms. While gene targeting in domestic species by using non-isogenic DNA as a source for targeting arms is possible (McCreath et al., 2000; Denning et al., 2001a and b; Kuroiwa et al., 2004; Marques et al., 2006; Richt et al., 2007), the use of isogenic DNA can largely improve the efficiency of gene targeting (te Riele et al., 1992). (iii) Increase the length of continuous exogenous homologous arms. The efficiency of gene targeting was generally found to be increased with the length of targeting arms in mouse ES cells (Hasty et al., 1991a). (iv) Use multiple cell lines; when targeting the CFTR (cystic fibrosis transmembrane conductance receptor) gene in pig fetal fibroblast cell lines, Rogers et al. (2008) demonstrated drastic differences in the targeting efficiencies between cell lines derived from littermate pig fetuses.
3.1.2 Tissue specificity and inducible promoters

As mentioned, the promoter used in a transgenic DNA construct determines when, where and to what extent the transgene is expressed. Hundreds of promoters can be isolated for the expression of transgenes, and are generally classified as constitutive promoters, tissue/cell-specific or Developmental stage-specific promoters and inducible promoters. Constitutive promoters, such as commonly used SV40 (simian virus 40 promoter), CMV (cytomegalovirus immediate-early promoter), PGK (mouse phosphoglycerate kinase 1 promoter) and CAGG (chicken β-Actin promoter coupled with CMV early enhancer) promoters for mammalian systems (Qin et al., 2010), can continuously drive transgene expression in all tissues and species. Tissue/cell-specific or developmental stage-specific promoters can restrict transgene expression to specific tissue(s) or only during certain developmental stages. For example, the 5.5-Kb osteopontin (OPN) promoter has been used to drive GFP expression in transgenic mice in the same cell-specific and developmental stage-specific manner as endogenous OPN expression (Higashibata et al., 2004). Inducible promoters, as their name suggests, may be activated by the presence of endogenous or exogenous factors. Exogenous factors include chemical compounds such as antibiotics or physical factors such as heat and light. For example, TRE promoter (tetracycline-responsive element promoter) can be activated by the rtTA (reverse tetracycline-controlled transcriptional activator) in a doxycycline-inducible manner (Qin et al., 2010). Antibiotic-induced promoters are the most commonly used in animal genetic modification because of easy manipulation. Inducible promoters provide a very useful tool in animal genetic engineering to turn on or off transgene expression in a particular tissue or at certain developmental stages.

3.1.3 Positive/negative selection strategies

Considering the rarity of a homologous recombination event relative to random integration of the targeting vector, an efficient targeting vector design should incorporate a good selection strategy, providing a powerful tool to improve the frequency of targeted colonies and reduce screening cell lines that result from random integration. Promoter-less gene targeting vector, also referred to the promoter-trapping method, has been used to enrich the gene targeting events in somatic cells in pigs and sheep (McCreath et al., 2000; Denning et al., 2001a and b). In a promoter-trapping vector, the selectable gene lacks its own promoter but it becomes activated from the target gene promoter after correctly integrating into the genome. In a fibroblast cell line, promoter-less vectors can enrich targeting frequency 5,000- to 10,000-fold (Hanson and Sedivy, 1995). Despite this potential improvement, the major limitation of the promoter-trapping method is that it requires active transcription of the targeted gene to drive expression of the selectable marker used in the targeting vector. Thus, if the target gene is only active in cell types that are difficult to culture, it is nearly impossible to target the gene locus using this method. Compared with promoter-trapping method, a more widely used strategy includes utilization of both positive and negative selection (PNS) (Jin et al., 2003; Kuroiwa et al., 2004; Richt et al., 2007). A positive selection gene (antibiotic-resistant gene such as neo) in the targeting vector is needed to select cells with an integrated construct a negative selection gene (cytotoxic genes such as the thymidine kinase (TK) gene or the diphtheria toxin A-chain (DT-A) gene) to further select against random integration event. The negative selection marker in the targeting vector usually is placed downstream of homologous arms and recombined away during the process of homologous recombination. The enrichment of the PNS selection is the ratio of
clones recovered with the positive selection only (PS) versus the positive and negative dual selections. The PNS strategy can be used to target both active and inactive gene loci. It has been shown that the targeting efficiency at the COL1A1 locus in fibroblasts by the promoter-trapping strategy is 15.7-fold higher than by PS only (Marques et al., 2006).

3.2 Delivery of DNA vector into cultured somatic cells
Following vector construction and preparation of the DNA construct for delivery into a somatic cell, it is important to identify an efficient method of DNA delivery into somatic cells as efficiency between delivery methods varies greatly. There are numerous methods to introduce an exogenous DNA construct into somatic cells, which can be categorized as liposome-mediated DNA transfer (Hyun et al., 2003a; Lee et al., 2005), electroporation (Dai et al., 2002; Ramsoondar et al., 2003; Watanabe et al., 2005) and viral-mediated delivery (Lai et al., 2002b; Rogers et al., 2008).

3.2.1 Liposome-mediated DNA delivery
Liposome-mediated DNA transfer can easily transfected a large number of somatic cells without the need of specialized equipment and expertise, compared with other methods. Lee et al. (2005) demonstrated the efficiency of gene transfection with a plasmid containing the enhanced green fluorescence protein gene into fetal-derived bovine fibroblast cells by lipids was significantly higher than that obtained by electroporation. They also validated that transfection efficiency in fetal-derived bovine fibroblast cells, regardless of the delivery methods, was significantly higher than delivering DNA into cumulus-derived fibroblast cells and adult ear skin-derived fibroblast cells, establishing that both delivery method and cell line origin affect the efficiency of gene transfection. Using liposome-mediated DNA delivery followed by SCNT, genetically modified pigs (Hyun et al., 2003a) and sheep (McCreath et al., 2000) have successfully been created.

3.2.2 Electroporation
In contrast to liposome-mediated DNA delivery, electroporation has been widely used for the delivery of exogenous DNA into the cytoplasm of somatic cells to generate genetically modified cell lines for nuclear transfer. Electroporation has been utilized to successfully provide genetically modified donor cells for SCNT to create transgenic cloned domestic animals, including cattle (Kuroiwa et al., 2004), goat (Yu et al., 2006; Zhu et al., 2009), pig (Dai et al., 2002; Lai et al., 2002a; Ramsoondar et al., 2003; Watanabe et al., 2005) and sheep (Denning et al., 2001a). Ross et al. (2010a) indentified optimal electroporation conditions (three 1 ms pulses of 300 V to 200 µL of 1x10⁶ cells/mL in the presence of 12.5µg DNA/mL), which can consistently deliver DNA vector into the 65-80% surviving porcine fetal fibroblasts and have been used to produce healthy, viable transgenic piglets (Ross et al., 2009b). In adult rhesus macaque fibroblasts, it has been demonstrated that electroporation can generate more transfected cells than liposome-mediated methods (Meehan et al., 2008), which is consistent with other similar comparisons (Yáñez and Porter, 1999). Of the numerous delivery methods, electroporation was demonstrated to have the greatest efficiency in generating targeted cell lines via homologous recombination (Vasquez et al., 2001). Targeting the hypoxanthine guanine phosphoribosyl transferase (HPRT) locus, Mir and Piedrahita (2004) demonstrated that the electroporation of a DNA construct with a nuclear localization signal into s-phase synchronized cells can increase targeting efficiency.
seventh fold and decrease random integration events 54-fold in primary fetal bovine fibroblasts. Later, Meehan et al. (2008) confirmed this method by successful gene targeting of the HPRT locus in adult rhesus macaque fibroblasts achieved by electroporation of S-phase synchronized cells with a construct containing a SV40 enhancer.

3.2.3 Viral-mediated delivery
Because viruses have the natural ability to stably transfec somatic cells with high efficiency, utilizing viral particles to delivery exogenous DNA into somatic cells has been widely successful. In contrast to liposome-mediated delivery and electroporation, which deliver linear, double-strand DNA into the cytoplasm of somatic cells, viral delivery of exogenous DNA delivers a high number of the linear, intact single-strand DNA molecules into the nucleus of cells. One report has demonstrated the efficient targeting of the PRNP gene encoding the prion protein PrP in bovine fetal fibroblasts by adeno-associated virus (AAV) vectors (Hirata et al., 2004). Also, the same transfection method followed by SCNT was used to successfully produce the CFTR-null and CFTR-DeltaF508 heterozygous pigs and CFTR-deficient ferrets (Rogers et al., 2008; Sun et al., 2008). Despite high transfection efficiency and production of transgenic cloned animals using viral-mediated delivery method, the need to produce high concentrations of virus particles in addition to limitations of the size of DNA capable of being delivered via virus limits the application of this method.

3.3 Selection and characterization of transgenic cell lines
3.3.1 Selection by marker
Following DNA construct delivery into somatic cells, transfected cells are cultured 24-48h in the absence of selection, followed by selection. Selection agents are chosen according to the DNA construct and added in cell-type specific concentrations into the cell culture medium. Typically, G418 (Geneticin) is used when the neomycin resistance gene is the positive selection marker and ganciclovir when using the TK gene for negative selection. Due to the limited lifespan of many of the somatic cell lines that are typically used for nuclear transfer and the significant amount of time to produce clonal colonies, it is important to perform the genetic screening by PCR or southern blotting as early as possible, prior to cell senescence.

3.3.2 Genotyping by PCR or southern blotting
Screening selected colonies by PCR for a gene targeting event typically involves using one PCR primer specific to the host genome sequence and the other primer specific to the selectable marker between the arms of homology in the targeting vector. This approach provides a simple, rapid and highly sensitive method to identify the gene targeting event in the transfected cells (Gómez-Rodríguez et al., 2008). Furthermore, PCR can be performed using the lysate from the small amount of cells, and also can be facilitated by pooled analysis of multiple cell lines. These types of PCR analysis sometimes require optimization as the amplicon is typically several thousand bp depending on the length of the targeting arms. Following the initial screening via PCR, the targeted colonies can be further expanded for analysis by southern blotting. A strategy for identifying targeted cells by southern blotting should be incorporated in the vector design. Two DNA probes on each side of the wild type gene, but outside the targeting vector, are designed to detect a change in fragment size resulting from either introduction or elimination. It is necessary to verify that the probes for southern blotting work well on wild-type genomic DNA from the somatic cells before
the targeting experiment. Also, it is important to perform southern blotting analysis using both probes to confirm the double-crossover event since homologous recombination can occur at only one end of the targeting vector (Hasty et al., 1991b; Moens et al., 1992). Of the methods of screening for gene targeting in somatic cells, southern blotting is considered to be the golden approach to identify correctly targeted colonies despite being time-consuming and relatively expensive compared to PCR approaches.

3.3.3 Fluorescence In situ hybridization
Fluorescence in situ hybridization (FISH) is most commonly used to identify the number of integration sites following random integration of a transgene. FISH has been successfully used to detect the number of bacterial artificial chromosome (BAC) sequences integrated and chromosomal location(s) in mouse ES cells (Yang and Seed, 2003). Although the chromosomal location can be shown directly by FISH, Gómez-Rodríguez et al. (2008) found that screening of BAC-based constructs by FISH can be prone to false positives because of small pieces of integrated DNA that are below the limits of detection by fluorescent hybridization.

3.4 SCNT using genetically modified somatic cells
Once the cell line containing the appropriate genetic modification has been identified, those cells can then be used for SCNT as described in Figure 1. SCNT is a process in which the nucleus of a somatic cell is transferred into the cytoplasm of an enucleated oocyte. The hereby reconstructed SCNT embryos can be activated to initiate development and then are transferred into a synchronized surrogate mother immediately or after short-term in vitro culture. In addition to the technical factors involved in the SCNT process, the status of the donor cells and the quality of unfertilized oocytes are considered to largely affect the overall efficiency of the SCNT. This point will be discussed more below.

4. Improvement of the efficiency of cell-based transgenesis via SCNT
Since cell-based transgenesis via SCNT relies extensively on both transgenic and SCNT techniques, the efficiency could be improved by increasing SCNT efficiency and/or gene transfer efficiency.

4.1 Factors affecting SCNT efficiency
SCNT is a technique that requires precise skills in micromanipulation. In addition to technical skills, numerous other factors also impact SCNT efficiency, including donor cell types, quality of the recipient oocytes, cell cycle synchronization of both donor cell and recipient cytoplasm, the epigenetic status of the donor cell, method of reconstructed zygote activation, epigenetic reprogramming following activation, in vitro culture conditions of reconstructed embryos and embryo transfer into surrogate mothers. Here, we will focus on the cell cycle synchronization and methods being used to improve nuclear remodeling and reprogramming during SCNT.

4.1.1 Type of cell and synchronization of cell and recipient oocyte
Different types of donor cells and the different origins of recipient oocyte have been successfully used to produce the cloned animals in domestic species (Table 2). Generally, nuclei from less differentiated donor cells demonstrate greater SCNT efficiency than those
from differentiated donor cells (Hill et al., 2000; Lee et al., 2003). SCNT embryos created from in vivo-derived MII oocytes have better developmental potential than in vitro-matured MII oocytes; and in vitro-matured oocytes from sexually mature animals have been demonstrated to more efficiently produce cloned embryos than oocytes in vitro-matured from pubertal animals (Lai et al., 2002a; Lee et al., 2003; Hyun et al., 2003b). Since the first SCNT animal was produced by transferring the nuclei from quiescent cells (G0), synchronization of the donor nuclei into G0/G1 is thought to be crucial to the success of SCNT (Wilmut et al., 1997). The G0 cells, with lower transcription activity and different chromatin configuration in contrast to the cells at other stages of the cell cycle, may be more responsive to factors inside the recipient oocyte cytoplasm that impact the nuclear remodeling and reprogramming process following SCNT. The cell cycle of cultured somatic cells can be synchronized by serum starvation, contact inhibition and chemical treatments (Cho et al., 2005; Gibbons et al., 2002). Serum starvation to induce the donor cells into G0 is widely used for the production of cloned transgenic animals (Table 2). However, recent studies have demonstrated that synchronizing the cell cycle of donor cells by serum starvation can cause apoptosis (Dalman et al., 2010) and reduce blastocyst production in cattle (Miranda Mdos et al., 2009). The production of the cloned transgenic calves from non-quiescent fetal fibroblasts demonstrated that the synchronization of the donor cells is not an absolute requirement for SCNT success (Cibelli et al., 1998). However, the relative cell cycle combination of both donor cells and recipient oocyte, not just donor cells, is thought to be important for the maintenance of correct ploidy and the subsequent development of reconstructed embryos (reviewed by Campbell, 1999).

4.1.2 Methods to improve nuclear remodeling and reprogramming
Following transfer of a donor nucleus into a recipient oocyte cytoplasm and subsequent activation, nuclear remodeling events of the chromatin structure, such as changes of DNA methylation patterns and histone modifications, result in the reprogramming of gene expression to recapitulate developmental patterns observed in a normal fertilized embryo (Whitworth and Prather, 2010). In contrast to less differentiated donor nuclei, the relatively high level of DNA methylation and low histone acetylation exist in the chromatin of the highly differentiated nuclei. These epigenetic modifications are used to maintain the temporal and spatial patterns of gene expression specific to the cell type or developmental stage. When differentiated nuclei are transferred into the enucleated oocyte cytoplasm, correctly establishing normal patterns of zygotic gene expression is crucial to the full term development of SCNT animals. However, numerous studies have demonstrated improper reprogramming of genes in embryos and tissues of domestic animals following SCNT (Wrenzycki et al., 2001; Pfister-Genskow et al., 2005; Aston et al., 2010; Ross et al., 2010b). Thus, various strategies are under development to facilitate and promote appropriate nuclear reprogramming of the transferred nucleus following nuclear transfer or to pre-program the genome of the donor nucleus prior to SCNT. Of these strategies, one widely used is to treat reconstructed SCNT embryos, but not the donor cells, with histone deacetylase inhibitors (HDACi), such as trichostatin A (TSA), 6-(1,3-dioxo-1H, 3H-benzo [de] isoquinolin-2-yl)-hexanoic acid hydroxyamide (Scriptaid), sodium butyrate and valproic acid. It has been demonstrated that histone deacetylase inhibitor treatment after SCNT can improve both in vitro development of SCNT embryos to the blastocyst stage and in vivo development to term following embryo transfer (Li et al., 2008; Cervera et al., 2009; Zhao et al., 2009a, 2010; Das et al., 2010; Himaki et al., 2010a; Miyoshi et al., 2010). However,
these treatments may be with some level of toxicity, as one group has reported that offspring from TSA-treated rabbit embryos did not survive to adulthood (Meng et al., 2009). The exact mechanism by which the HDACi treatment significantly improves the cloning efficiency remains largely unknown, although it has been shown to increase levels of global histone acetylation after HDACi treatment which may subsequently change the structure of chromatin and improve nuclear reprogramming (Shi et al., 2008; Iager et al., 2008; Zhao et al., 2010; Das et al., 2010).

Accruing investigations have demonstrated that abnormal DNA methylation patterns contribute to the lower developmental competency of SCNT derived embryos (Kang et al., 2001, 2002; Bourc’his et al., 2001; Santos et al., 2003; Wrenzycki et al., 2006), suggesting the inability of oocyte to fully restore the DNA methylation pattern of differentiated donor nuclei to that of normal totipotent 1-cell stage embryos. Thus, the second method used to assist epigenetic reprogramming is to reduce the DNA methylation level in donor cells or reconstructed embryos by treating them with the DNA methyl-transferase inhibitor such as 5-aza-2′-deoxycytidine (5-aza-dC). Unfortunately, previous studies have demonstrated that 5-aza-dC treatment of donor cells or cloned embryos does not improve the in vitro and in vivo development of SCNT derived embryos (Enright et al., 2005; Tsuji et al., 2009). However, combining the treatment of donor cells and embryos with both TSA and 5-aza-dC resulted in improved blastocyst development (Ding et al., 2008). Furthermore, an additional study has demonstrated enhanced gene targeting frequency in ES cells with low genomic methylation levels, suggesting the epigenetic status of targeted loci may influence the efficiency of gene targeting by affecting the accessibility for the homologous recombination machinery (Domínguez-Bendala and McWhir, 2004).

An additional strategy to promote developmental reprogramming of cloned embryos is to treat them with latrunculin A (LatA), an actin polymerization inhibitor. One group has reported that post-activation treatment with LatA is effective to improve in vitro developmental capacity of gene-modified cloned miniature pig embryos and embryos treated with LatA have the ability to develop into fetuses (Himaki et al., 2010b). Pre-reprogramming donor nuclei prior to SCNT has also been attempted. Rathbone et al (2010) reported that pretreatment of permeabilized ovine fetal fibroblasts with a cytoplasmic extract produced from germinal vesicle (GV) stage *Xenopus laevis* oocytes improves the live birth rate, but not development to blastocyst stage or pregnancy rate following embryo transfer.

4.2 Methods to improve gene transfer efficiency

Production of transgenic domestic animals has been widely accomplished, however, several limitations remain. Typically, plasmid based DNA constructs are limiting in the size of exogenous DNA to transfer and creating animals with targeted genetic modifications has been significantly more challenging. Thus, it is important to continue development of new strategies that broaden application and increase the efficiency of creating targeted genetic modifications in domestic animals.

4.2.1 Artificial chromosomes as DNA transfer vector

In contrast to plasmid based vector, artificial chromosomes have the capacity to carry Megabase-sized pieces of DNA that are maintained as autonomous, replicating chromosomes. Artificial chromosome vectors include a centromere, two telomeres and origins of replication (Robl et al., 2007). A 10 Mb human artificial chromosome (HAC) vector
containing the entire unarranged sequences of the human immunoglobulin heavy and light chain loci (1-1.5 Megabase for each locus) have been transferred into bovine fibroblasts using a microcell-mediated chromosome transfer approach. Following SCNT using selected cells, trans-chromosomal cloned chromosome transfer approach were produced that expressed human immunoglobulin proteins in the blood. HAC was retained as an independent chromosome with the proportion of cells ranged from 78 to 100% in most animals and HAC retention rate has not changed over several years. This system provides a useful tool to produce human therapeutic polyclonal antibodies using trans-chromosomal cloned domestic animals (Kuroiwa et al., 2002; Robl et al., 2007). In domestic animals, the swine artificial chromosome (SAC) (about 310 kb) containing pig centromeric DNA and the neomycin resistance gene was constructed and introduced into pig cell lines, and one positive clone was characterized, showing the possibility for producing transgenic pigs for xenotransplantation and other purposes (Poggiali et al., 2002).

4.2.2 Zinc finger nucleases (ZFNs) and transcription activator-like effector nucleases (TALNs)

The low frequency of homologous recombination hampers rapid progress and wide application of gene targeting in domestic animals. The generation of a site-specific double-stranded DNA break (DSB) within the desired locus can facilitate gene targeting by resulting in additions and deletions causing inactivation of gene function. Naturally occurring DNA-binding proteins, including zinc finger proteins (ZFPs) and meganucleases, have been engineered to bind site-specific DNA sequence. Zinc finger nucleases (ZFNs) combine the specific DNA-binding domain (ZFP) with the non-specific cleavage domain of the restriction endonuclease FokI and offer powerful tools to create a site-specific DSB to facilitate local homologous recombination. The ZFN induced DSB can lead to incorporating exogenous DNA in a site specific manner by utilization of a homologous recombination targeting vector that overlaps with the DSB region. Additionally, DSBs repaired by non-homologous end-joining (NHEJ) can result in loss of a single nucleotide, multiple nucleotides, or small regions; all capable of rendering a targeted gene dysfunctional. For increasing the specificity of DNA binding, multiple zinc fingers, each recognizing and binding to a 3-bp sequence of DNA nucleotides can be linked in tandem to recognize a unique genomic locus. In human somatic cells, custom-designed ZFNs yielded more than 18% targeting efficiency at the X-linked interleukin-2 receptor gamma gene locus and about 7% of the cells possessed a bi-allelic gene modification (Urnov et al., 2005). ZFNs can also promote the addition of novel DNA sequence into a targeted endogenous locus of human cells at a frequency ranging from 5% to 15% depending on the size of extra-chromosomal DNA (Moehle et al., 2007). Thus, the efficiency of gene targeting using ZFNs offers the possibility of gene therapy for human genetic disease and an approach for improvement of genetic engineering in domestic animals. Recently, targeted gene disruption of exogenous EGFP gene was achieved in porcine somatic cells using ZFNs (Watanabe et al., 2010) and transgenic EGFP knockout pigs were produced using ZFNs followed by SCNT (Whyte et al., 2011).

The appropriate design of a site-specific ZFN is critical to successfully introduce ZFN-mediated genetic modifications. Of the available zinc-finger engineering methods, modular assembly is the most easily performed method, but is also associated with high failure rates to yield a functional three-zinc finger array for the majority of potentially targetable sites (Ramirez et al, 2008). The second method is to combine selection-based methods with ZFNs
made using modular assembly. While effective, this method is labor intensive and requires additional expertise. The third method, referred to as OPEN (Oligomerized Pool E NGineering) is based on bacterial 2-hybrid (B2H) selection and has been proven to be a rapid platform for plant and human cells with high targeting efficiency (ranging from 1 to 50% at different loci) and less toxicity compared to modular assembly system. However, utilization of OPEN requires an archive of pre-selected zinc-finger pools and E. coli selection (Maeder et al., 2008). Furthermore, due to the challenge of engineering the endonucleases, orthophenanthroline (OP, a DNA cleaving molecule) was conjugated with triplex-forming oligonucleotides (TFOs, sequence-specific binding capacity) to induce targeted DSBs and stimulate mutations at the target site in approximately 10% of treated human cells (Cannata et al., 2008). TFO conjugating to OP or other DNA cleaving molecules may provide a useful tool to induce targeted gene modification because triplex-forming sequences are frequent in mammalian genes. While ZFN-driven gene targeting can be much more efficient than homologous recombination-based methods, the design and development of highly specific ZFNs remain difficult because of the lack of a simple correspondence between amino acid sequence and DNA recognition sequence.

Recently, several groups have shown that transcription activator–like effectors (TALEs) from the bacterial genus Xanthomonas contain a central domain of tandem repeats that can be readily engineered to bind virtually any DNA sequence (Boch et al., 2009; Christian et al., 2010; Morbitzer et al., 2010). The structure of the central protein domain, highly conserved in all the known TALEs, includes 17.5 tandem repeats with 34 amino acids per repeat. In each repeat monomer of a TALE, only amino acid positions 12 and 13 are hypervariable (repeat variable diresidues) (Boch et al., 2011), which can specifically recognize a single nucleotide in the target site (Boch et al., 2009; Moscou et al., 2009). Thus, the correspondence between each repeat variable diresidues and the binding nucleotide in DNA sequence opens the possibility to create novel sequence-specific DNA binding proteins by rearrangement of TALE repeats. The engineered hybrid TALE nucleases (TALNs), produced by fusion of the FokI endonuclease domain with the high-specificity DNA-binding domains of TALEs, can bind and create targeted DSBs in tobacco and yeast (Mahfouz et al., 2011; Li et al., 2011), showing the feasibility of engineering TALE-based hybrid nucleases capable of generating site-specific genome modification. Recently, Miller et al. (2011) reported the generation of discrete edits or small deletions within endogenous human NTF3 and CCR5 genes and the insertion of 46-bp sequence at CCR5 locus into the genome of human K562 cells using designed TALNs, demonstrating the effective application of TALNs to modify endogenous genes. While the simple DNA-binding code of TALEs enables easier design strategies as compared to ZFPs, the repetitive nature of TALE DNA-binding domains results in difficulty to efficiently synthesize new TALEs by currently used vector construction methods. To overcome this problem, Zhang et al. (2011) recently developed a new strategy to construct repeat domains of TALEs by hierarchical ligation.

4.3 Induced pluripotent stem (iPS) cells

Owing to the lack of ES cells in domestic animals, it is difficult to replicate strategies routinely used to create genetically modified mice. As an alternative, cell-based transgenesis via SCNT is currently used to produce genetically modified domestic animals. Recent advancements in the ability to generate induced pluripotent stem (iPS) cells may open another potential strategy to improve the efficiency of SCNT in domestic animals. Induced pluripotent stem cells in mice and human were successfully generated by reprogramming
somatic cells with viral delivery of a combination of four defined transcription factors including Sox2, Oct4, Klf4, and c-Myc or Sox2, Oct4, Nanog, and Lin28 (Takahashi and Yamanaka, 2006; Takahashi et al., 2007; Yu et al., 2007). The iPS cells are similar to ES cells in morphology, biochemistry, gene expression and the ability to differentiate into many cell types and self renew (Wernig et al., 2007; Lowry et al., 2008). Furthermore, subsequent studies have optimized existing procedures and discovered novel reprogramming protocols to generate the iPS cells, including non-integrating viruses (Stadtfeld et al., 2008), non-viral vectors (Okita et al., 2008), non-integration episomal vectors (Yu et al., 2009) and RNA-induced reprogramming (Warren et al., 2010), which greatly decrease the biosafety concerns associated with the application of iPS cells. The use of iPS cells can benefit animal transgenesis in several aspects. (i) Stable genetic modification in iPS cells may be more efficient compared to somatic cells as is the case with ES cells. (ii) Genetically modified iPS cells can be used to produce chimeric animals since it has been reported that iPS cells produce viable, live-born and fertile mice offspring through tetraploid complementation (Zhao et al., 2009b; Boland et al., 2009). (iii) The use of genetically modified iPS cells as donors may increase the efficiency of cell-based transgenesis via SCNT owing to the pluripotent status of iPS cells. (iv) In contrast to the limited lifespan of somatic cells, true iPS cells are immortalized. These advantages, coupled to successful derivation of iPS cells from domestic animals (Esteban et al., 2009; Ezashi et al., 2009; Wu et al., 2009) presents a new opportunity to produce transgenic animals using iPS cells.

5. Summary

While the potential opportunities of transgenic domestic animals in biomedicine and agriculture are significant, current procedures, including cell-based transgenesis via SCNT, to produce genetically modified domestic animals are not without limitations. The combination of new technologies, including ZFNs/TALNs to enhance targeted genome modification and iPS cells and other strategies to improve epigenetic remodeling of SCNT embryos, represent pathways for improving the success rates of current genome manipulation strategies resulting in transgenic domestic animals. These modern approaches may have limitations of their own, such as the difficulty and high cost to design, produce and validate the target-specific ZFPs, constructing custom-designed TALEs, and maintenance of iPS cells. However, despite these limitations, we expect to see these strategies become widely utilized as a result of the potential opportunities that utilization of these strategies offers to the field of targeted genome manipulation in domestic animals.

IX transgenic sheep produced by transfer of nuclei from transfected fetal fibroblasts. Science 278: 2130-2133.

This innovative book integrates the disciplines of biomedical science, biomedical engineering, biotechnology, physiological engineering, and hospital management technology. Herein, Biomedical science covers topics on disease pathways, models and treatment mechanisms, and the roles of red palm oil and phytomedicinal plants in reducing HIV and diabetes complications by enhancing antioxidant activity. Biomedical engineering covers topics of biomaterials (biodegradable polymers and magnetic nanomaterials), coronary stents, contact lenses, modelling of flows through tubes of varying cross-section, heart rate variability analysis of diabetic neuropathy, and EEG analysis in brain function assessment. Biotechnology covers the topics of hydrophobic interaction chromatography, protein scaffolds engineering, liposomes for construction of vaccines, induced pluripotent stem cells to fix genetic diseases by regenerative approaches, polymeric drug conjugates for improving the efficacy of anticancer drugs, and genetic modification of animals for agricultural use. Physiological engineering deals with mathematical modelling of physiological (cardiac, lung ventilation, glucose regulation) systems and formulation of indices for medical assessment (such as cardiac contractility, lung disease status, and diabetes risk). Finally, Hospital management science and technology involves the application of both biomedical engineering and industrial engineering for cost-effective operation of a hospital.
