Effects of Blood Transfusion on Retinopathy of Prematurity

Ebrahim Mikaniki, Mohammad Mikaniki and Amir Hosein Shirzadian

Babol University of Medical Sciences

Iran

1. Introduction

Retinopathy of prematurity (ROP) is a vasoproliferative retinal disorder, which represents the main cause of visual impairment and blindness in preterm infants (Drack, 1998). ROP develops in 84% of premature survivors born at <28 weeks of gestation (Palmer et al, 1991). Fortunately, it resolves in most cases (80%) without visual loss from retinal detachment or scars (Palmer et al, 1991; Cryotherapy for retinopathy of prematurity cooperative group, 1994). In this study, the total ROP incidence was 0.17% overall and 15.58% for premature infants with length of stay of more than 28 days (Lad et al, 2009). The increased survival of very small premature infants has led to the resurgence of this potentially blinding disease (Kinsey et al 1977; Shohat et al 1983). The pathogenesis of ROP isn’t fully known. The altered regulation of vascular endothelial growth factor from reported episodes of hyperoxia and hypoxia is an important factor in the pathogenesis of ROP (Chow et al 2003). Apparently, any severe physiologic stress may damage the developing capillaries in immature retina and in response to ischemia, new vessel (neovascular) growth resumes (Phelps, 1992). ROP appears to be a multifactorial disease. Given the multifactorial nature of ROP and close relation of the most risk factors to prematurity, it is difficult to define the specific role of any individual factor in the pathogenesis of ROP (Hesse et al 1997).

Blood transfusion has been identified as a risk factor for ROP in several studies (Shohat et al, 1983; Cats & Tan KEW, 1985; Clark et al, 1981; Cooke et al, 1993; Sacks et al, 1981; Yu & Hookham & Nave, 1982). Some investigator, however, could not confirm this associating (Bossi et al, 1984; Brown, 1987; Lechner & Kalina & Hodson, 1977). The damaging effects of blood transfusion on the retina are mediated via an increase in free iron that may catalyze fenton reactions, which produce free hydroxyl radicals capable of damaging the retina (Sullivan, 1988). Preterm infants are particularly susceptible to iron overload because of frequent transfusions and low levels of iron – binding proteins (Sullivan, 1988). In an effort to limit the risks associated with RBC transfusion, many neonatal units have adopted more restrictive guidelines for transfusing preterm infants (Widness et al, 1996; Alugappan & Shattuck & Malloy, 1998; Maies et al 2000; Franz & Pohlandt, 2001), but the safety or potential benefits of restricting transfusions have not been adequately tested.
2. Retinopathy of prematurity

2.1 History

ROP was first described by Terry in 1942 as retrolental fibroplasias (Terry, 1942) and a few years later was recognized as one of the leading causes of infant blindness (Zacharias, 1952). The indiscriminate use of oxygen from the 1940s to the mid-1950s was associated with a very high incidence of ROP. After the widespread adoption of the New York city health departments recommendation to restrict supplemental O2 concentrations to 40% , the incidence of ROP decreased dramatically (James & Lamman, 1976). During the 1960s it became obvious that although ROP incidences had decreased, the oxygen restriction appeared to be associated with a significant increase of infant morbidity and mortality from hyaline membrane disease (Avery & Oppenheimer, 1960) and brain injury (McDonald, 1963). Oxygen supplementation was therefore liberalized in the late 1960s, and incidence of ROP began to rise again.

In the late 1960s, the incidence of ROP began to rise again. This increase continued during the 1970s and 1980s, likely as a result of the improved survival rate of very low birth weight infants associated with advances in neonatal medicine (Valentine et al, 1991). However, with improved technology and new techniques in neonatal nursing care, very low birth weight infants are now surviving with decreasing morbidity, and it is possible that the recent advances, that produced this change have also had an effect on ROP incidence (Bullord et al, 1998).

2.2 Incidence and risk factors

Kinsey et al found the incidence of ROP to be 38% in infants weighing 1200 g or less (Kinsey et al 1977). The CRYO-ROP trials reported an incidence of 65.8%, infants weighing less than 1251 g and 81.6% in those less than 1000 g (Palmer et al, 1991). Many other studies reported ROP incidence ranging from 10% to 66% in infants with low birth weights in the United States and worldwide (Shohat et al 1983; Cats & Tan KEW, 1985; Bullord et al, 1998; Fledelius & Dahl, 2000; Akkoyun et al, 2006; Rowlands et al, 2001; Hussain & Clive & Bhandori, 1999; Wright et al, 1998; Custick et al, 2006; Yang et al, 2006).

Chiang and associates have reported that the incidences of ROP were 20.3%, 27.3% and 33.2% in infants with a length of stay of more than 28 days with birth weight of less than 1500 g, 1200 g and 1000 g respectively (Chiang et al, 2004).

More recently Lad et al. in a large retrospective study based on the national Inpatient sample from 1997 through 2005 reported ROP incidence of 15.58% for premature infants with length of stay of more than 28 days (Lad et al, 2009).

Several risk factors have been associated with ROP. The major risk factors are prematurity (low birth weight, low gestational age at delivery). An inverse relationship was found between birth weight and the incidence and severity of retinopathy of prematurity (Lad et al, 2009; Kinsey et al 1977; Shohat et al, 1983; Bossi et al, 1984; Gunn et al, 1980; Hammer et al, 1986; Patz, 1969). This finding emphasize, that the degree of immaturity of the eye is the main predictive factor for the devolvement of ROP.

Immature and underdeveloped retinal blood vessels in premature infants may be more vulnerable to postnatal environmental influences such as hyperoxic or hypoxic tissue injury,
Effects of Blood Transfusion on Retinopathy of Prematurity

hypercarbia, and metabolic acidosis (Quinn, 1998). Moreover, these adverse conditions have a better opportunity to affect retinal vascular development if more development is left to occur under their influence. For many years it was thought that oxygen therapy increased the risk of ROP in preterm infants, however (Reynolds et al, 1998), ROP can occur even with careful control of oxygen therapy (Akkoyun et al, 2006). In fact, the role of oxygen has been overemphasized in the past and excessive oxygen administration has not been identified as an independent risk factor (McColm & Fleck, 2001). A reasonable working hypothesis is that the developing retina is highly sensitive to any disturbance in its oxygen supply either hyperoxic or hypoxic (Lucey & Dangman, 1984).

Other proposed risk factors that are under study and may not be causally linked to ROP include: metabolic acidosis (Bossi et al, 1984), metabolic alkalosis (Shohat et al, 1983), hypercarbia (Bauer & Windmayer, 1981), hypoxia (Brown, 1987), transfusions (Brown, 1987; Clark et al, 1981), light (Glass et al, 1985), intraventricular hemorrhages (Brown, 1987), white race (Saunders et al, 1997), chronic lung disease (Biglan et al, 1984), seizures (Biglan et al, 1984), sepsis (Gunn et al, 1980), xanthine administration (Hammer et al, 1986), magnesium and copper deficiency (Caddell, 1995), Vitamin E deficiency (Owens & Owens, 1949), selenium deficiency (Papp & Nemeth & Pelle, 1993), and multiple gestations (Bossi et al, 1984). Any change that affects the incidence or nature of one or more of these risk factors might also affect the incidence and severity of ROP.

2.3 Pathogenesis

ROP is a condition confined to the immature retinal vascular system. The likelihood of developing retinopathy is related to the degree of vascular development so that once the retina is fully vascularized the risk of developing ROP has passed. Normally, retinal vascular development progresses from the 16th week of gestation to the 40th week in a central to peripheral wave at a rate of about 0.1 mm/day (Payne & Patz, 1979).

ROP alters this normal developmental progression, which instead follows a two-staged pathophysiologic course: an initial phase of vasoconstriction and arrested vessel growth, followed by a second phase of abnormal vessel proliferation. The onset of ROP generally requires two conditions. The first is incomplete retinal vascular development. ROP incidence and severity is directly proportional to the degree of prematurity that is, ROP outcome correlates with the size of the area of retinal avascularity at onset (Kinsey et al, 1977, Schaffer et al, 1993, Kalina & Kari, 1982). The second condition involves exposure of the developing retina to an abnormal environmental influence and several have been suggested (Quinn, 1998). Most prominent among these is retinal hyperoxia resulting from postnatal hyperoxemia in infants receiving supplemental oxygen to compensate for inadequate pulmonary function. This condition, alone or in combination with other as yet unidentified results, leads to cessation of retinal vessel development. The retinal vasculature then enters a quiescent phase for days or weeks, while the formation of a ridge-like structure develops, separating the central vascularized region of the retina from the peripheral avascular region. This structure, which is pathognomonic of ROP, historically consists of mesenchymal and endothelial cells. Concomitant development of retinal neurons with advancing postnatal age results in increasing oxygen requirements, which cannot be met by attenuated vessel compliment in retinal hypoxia (Weiter & Zucherman & Schepens, 1982). As a result of hypoxia another as yet undefined stimulus, angiogenic growth factor induction occurs,
followed by rapid growth of new vessels within the ridge. The new vessels can regress by involution and remodeling into a nearly normal vascular pattern or the growth can progress to extraretinal neovascularization (Nelson, 1790). These extraretinal vessels are weak and prone to leakage. The result is vitreous hemorrhage, scarring and contraction, leading to retinal folds or detachments and vision (loss Foos, 1985).

ROP is called stage 1 when the growing vessels end abruptly at a noticeable line separating the vascular and avascular retina takes on height and width, it becomes a ridge and casts a little shadow; the ridge is stage 2 ROP. When the bunched up vessels in a stage 2 eye erupt into the vitreous, The ROP becomes stage 3 and can be of variable severity. The greater the amount of extraretinal neovascularization vertically, and the greater the extent of the disease’s spread around the retina, the stage 3 will be more severe. If the ROP progresses further, exudative and tractional retinal detachments occur and may be partial (stage 4) or complete (stage 5) (Phelps, 1992).

In the premature infants, the developing capillaries without a basement membrane or supporting predicts completely ablate during a prolonged period of absent retinal flow; it remains in dispute whether the vascular ablation in the premature infants is due to direct oxidative injury of the growing endothelium (Chan-Ling & Gock & Stone, 1995) or is nearly the consequence of prolonged vasoconstriction due to a disturbed auto regulatory mechanism of the retinal vessels (Ashton & Cook, 1954). The level of antioxidative in the immature retina is relatively low and therefore oxygen radicals which accumulate in the preterm baby’s retina may play an important role in the pathogenesis of ROP (Hesse et al, 1997).

2.4 Terminology of ROP
The severity of ROP is described by four parameters: stage, location, extent and plus disease (table 1).

2.5 Screening for ROP
Since 1988, following the demonstration by the CRYO-ROP trial, severe ROP can be successfully treated so the ophthalmologists have had a duty to screen for this condition. The focus of screening is to identify ROP that requires treatment, at the appropriate point in the disease progression. The indication for treatment which has been reported in the CRYO-ROP study is threshold ROP. The term threshold denotes the ROP stage at which spontaneous and complete resolution is unlikely and the risk of blindness is predicted to be close to 50% (Cryotherapy for retinopathy of Prematurity Cooperative Group, 1988). The CRYO-ROP study divided all the diseases of the stage 3 into two categories: pre-threshold (or moderate ROP) and threshold (or severe ROP). Any disease of the stage 3 less than threshold was considered pre-threshold. Threshold ROP was defined as stage 3 ROP in zones one and two, in the presence of plus disease. Further studies such as that published recently by the Early Treatment for Retinopathy of Prematurity Cooperative Group (ETROP) recommends treating eyes before threshold because the outcomes of some eyes treated once they have develop threshold disease has been poor (ETROP, 1997).

3. Blood transfusion in preterm infants

Preterm infants, especially those with very low birth weight (VLBW) prematurity, often need multiple blood transfusions during hospitalization. Over 50-80% of VLBW preterm infants receive at least one blood transfusion during their neonatal intensive care unit (NICU) stay (Strauss, 1997). In addition to phlebotomy losses causing low hematocrit, most VLBW infants develop the anemia of prematurity (AOP) a hypoproliferative anemia marked by inadequate production of erythropoietin (EPO). Treatment of AOP include red blood cell transfusions which are given to preterm infants based on indications and guidelines (hematocrit/ hemoglobin levels, ventilation and oxygen) that are relatively non-specific (Bishara,2008).

Transfusions to VLBW premature infants could increase weight gain, improve oxygenation and decrease lactic acidosis (Ohls, 2000). The complications and potential risk of blood transfusions include blood – transmitted infection, metabolic and cardiovascular complications, graft versus host disease, iron overload and increased oxidative stress, which
are thought to be related to complications in premature infants such as chronic lung disease (CLD) and retinopathy of prematurity (ROP) (Cooke et al., 1997; Saugstad, 2003; Englert et al., 2001; Wheatley et al., 2002) considering the available evidence, many neonatal units have adopted more restrictive transfusion guidelines to reduce the frequency of transfusions and donor exposure (Windes et al., 1996; Alagappan & Shattuck & Malloy, 1998; Maier et al., 2000; Franz & Pohlandt, 2001). But, these changes in practice have not been accompanied by systematic examination of the safety or potential benefits of restricting transfusions. Limiting RBC transfusion in preterm infants may reduce the potential risk of transfusion, but the resulting low hemoglobin levels may result in the morbidities associated with chronic anemic hypoxemia as recommended by some studies that advocate more than liberal transfusion guidelines to prevent apnea (Ross et al., 1989), to foster weight gain (Meyer & sive & Jacobs, 1993). More recent trials have been performed to determine the safety and efficacy of more restrictive transfusion guidelines.

Bifano was the first to evaluate neonatal transfusion guideline in prospective fashion [76]. This study compared the clinical outcomes of two groups of Extremely Low Birth Weight (ELBW) infants who were randomly assigned to restrictive or liberal transfusion criteria, based on hemoglobin thresholds for transfusion. There were no differences between groups in growth, morbidities, or mortality during hospitalization. At 12 months follow up, there were no differences in overall neurodevelopmental impairment. This study suggested that a restrictive transfusion strategy was not associated with adverse outcomes.

Bell et al. conducted a randomized trial of liberal versus restrictive guidelines for bronze baby syndrome (BBS) transfusion in preterm infants and showed that restrictive transfusions may be harmful to preterm infants in the restrictive group which had a greater incidence of intraparenchymal brain hemorrhage or periventricular leukomalacia and more frequent episodes of apnea (Bell et al., 2005).

Bednorek et al. in a prospective study examined the relationships of high and low transfusion practice styles on neonatal outcomes (Bednorek et al., 1998). Multivariate analyses showed that infants cared for in the lower transfer NICU did not have an increased risk for several adverse outcomes including IVH, NEC, BPD, Lesser weight gain, and longer hospitalizations. Kirpalani et al., performed a study to determine whether extremely low birth weight infants transfused at lower hemoglobin thresholds versus higher thresholds have different rates of survival or morbidity at discharge (Kirpalani et al., 2006). These investigators concluded that, in ELBW infants, maintaining a higher hemoglobin level result in more infants receiving transfusions but confer little evidence of benefit. This study provided evidence that transfusion thresholds in ELBW infants can be moved downward at least 10g/L, without incurring a clinically important increase in the risk of death or major neonatal morbidity.

However, most of the neonatal studies published up to the present measured what infants received, regardless of actual need for red cells. Transfusion guidelines and practices would benefit from studies that identify a useful transfusion marker, preferably one that requires minimal to no blood (Ohls, 2008).

4. The effect of blood transfusion on ROP

The role of blood transfusions as a risk factor for ROP was first suggested by Shohat et al. (Shohat et al. 1983), and other authors subsequently confirmed this association (Shohat et al.
Effects of Blood Transfusion on Retinopathy of Prematurity

1983; Cats & Tan KEW, 1985; Clark et al, 1981; Cooke et al, 1993; Sacks et al, 1981; Ebrahim Mikaniki et al, 2010; Yu & Hookham & Nave, 1982), some investigators, however, could not confirm it (Bossi et al, 1984; Brown, 1987; Cooke et al; Lechner et al, 1977). Multivariate regression analysis found that only gestational age and frequency of blood transfusions are independently associated with the risk of occurrence of ROP (Cooke et al, 1993). They reported a 9% increase in the risk of ROP with each transfusion given (95% CI 1.0-1.18). But data on iron metabolism were not analyzed and no information was given about the actual volume of transfused blood. Hesse et al demonstrated by the same statistical method, that blood transfusions are an independent risk factor for ROP. In this study, the relative risk of developing ROP was 6.4 (95% CI 1.2-33.4) for infants who received 16-45 ml/kg, and 12.3 (1.6-92.5) for those who had received more than 45 ml/kg of blood (reference, 0-15 ml/kg) (Hesse et al, 1997). In contrast, there was no independent relationship between ROP and any of the parameters on iron metabolism analysis. Inder et al after multivariate regression analysis, showed that an elevation of serum iron and transferring saturation at 7 days of age is associated with an increased risk of ROP: they could not demonstrate an independent role of blood transfusions as a risk factor for ROP, but demonstrated that the iron status and the amount of transfused blood are highly correlated factors (Inder et al, 1997). Bossi et al, in another study, could not confirm an independent role of blood transfusion on development of ROP (Bossi et al, 1984).

Brooks et al, through a randomized, controlled trial, found that there was no association between hemoglobin or hematocrit ratios and ROP incidence or severity and transfusion limitation policy do not import a significant different risk for ROP (Brooks et al 1999). However in this study, the risk of ROP was related to the number and not the volume of blood transfusion, and the incidence of ROP in the studied population was so high (76%) that it seems to be difficult to decrease the occurrence of ROP only by limiting the blood transfusions. More recently, Dani et al showed that gestational age, blood transfusion volume and iron load by transfusions are associated with the risk of occurrence of ROP in infants with a birth weight of less than 1250 g. In this study, logistic regression analysis demonstrated that transfusion volume during the first week (OR 1.16; 95% CI 1.03-1.3) and during the first 2 months of life (OR 2.93; 95% CI 1.52-5.62), and iron intake during the first week of life (OR 1.15; CI 1.01-1.32) and during the first 2 months of life (OR 2.93; 95% CI 1.52-5.62) were associated with the development of ROP[87]. Two mechanisms by which blood transfusion could contribute to the development of ROP are discussed. First, Transfusions increase oxygen carrying capacity and a decrease in oxygen affinity caused by an increase in the proportion of adult hemoglobin. Second, transfusion increase iron load.

Sullivan pointed out that the transfusion of 10 ml of packed red blood cells will increase the premature infant's total body iron by 20%, and that packed red blood cells contain 450 times as much hemoglobin iron as the plasma total iron-binding capacity (Sullivan, JL, 1988). This, in conjunction with the reduced iron-binding capacity of preterm infants (due to their low transferring and ceruloplasmin levels) and postnatal depression of erythrocyte production, makes preterm infants who are repeatedly transfused extremely susceptible to an accumulation of increased amounts of free iron. Free iron could catalyze Fenton reactions which produce highly reactive oxygen-derived free radicals and are assumed to play an important role in the pathogenesis of ROP.
5. Conclusion

The increased survival of very small premature infants in modern NICUs led to increasing the incidence of ROP (Gibson et al, 1990; Gibson et al, 1990). Since ROP may produce serious sequel of infant blindness, all efforts must be made to prevent the development of advanced ROP. Identification of ROP risk factors will help to understand and predict ROP development in premature newborns (Akkoyun et al, 2006). One such risk factor may be multiple blood transfusions. Studies on the role of blood transfusion in ROP however have been hampered by the multifactorial nature of this disease and by the fact that most risk factors for ROP, including blood transfusions, are closely related to prematurity and are thus highly interdependent. This makes it difficult to define the specific role of any individual factor in the pathogenesis of ROP (Hesse et al 1997).

Using multivariate regression analysis, which provides a helpful tool in such a situation, some studies demonstrated that blood transfusion had a strong and dose-dependent influence on the development of ROP (Hesse et al 1997; Cooke et al, 1993; Dani et al, 2001). Otherwise, some investigators reported that the limitation of blood transfusion dose not affect ROP incidence (Bossi et al, 1984; Brooks et al 1999).

The reported mechanisms by which blood transfusions could contribute to the development of ROP are (1) the increase of Oxygen delivery to the retina (James&Greenough&Naik, 1997) due to lower oxygen affinity of adult hemoglobin in pack red cell (Cooke et al, 1993), and (2) the secondary iron overload.

The reduced iron-binding capacity of preterm infants due to their low transferring levels (Scott et al, 1975) makes preterm infants who are repeatedly transfused extremely susceptible to an accumulation of increased amounts of free iron. This problem catalyze Fenton reactions which produce free hydroxyl radicals capable of damaging the retina (Wardle et al, 2002). Despite a strong and independent association between ROP and blood transfusions, parameter suggestive of increased free iron, such as low transfusion or high ferritin levels, there not found to be independently associated with ROP in the one of related studies (Hesse et al 1997). It cannot be concluded from this data that a more restrictive transfusion policy will reduce the incidence of ROP, particularly as there is evidence that low levels of tissue oxygenation, which would be expected if VLBW infants are transfused less frequently, may also be a risk for ROP (Bauer & Windmayer, 1981). Otherwise, transfusion practices may differ considerably among both institutions and individual physicians because of a lack of uniformly accepted physiologic or evidence-based transfusion criteria (Brown & Berman & Luckey, 1990).

Decisions about transfusing VLBW infants with RBCs should be based on the risks and benefits of applying various transfusions guidelines and further refining based on the clinical status of individual infants. Recent studies suggests that frequent transfusions did not offer a detectable advantage and restricted transfusion did not have an increased risk for major brain injury as reported in previous studies (Ross et al, 1989; Chen et al, 2009). Albeit, these results must be interpreted with caution, because they may be related to other co practices in the specific NICU.

Further studies will be required to clarify whether as reduction in the number of transfusions will ultimately result in a reduced incidence of ROP without any significant difference in clinical outcome.

Blood Transfusion in Clinical Practice focuses on the application of blood transfusion in different clinical settings. The text has been divided into five sections. The first section includes a chapter describing the basic principles of ABO blood group system in blood transfusion. The second section discusses the use of transfusion in various clinical settings including orthopedics, obstetrics, cardiac surgery, etc. The third section covers transfusion transmitted infections, while section four describes alternative strategies to allogenic blood transfusion. The last section speculates over immunomodulatory effects of blood transfusion.
