Pathophysiological Approach to Acid Base Disorders

Absar Ali
Aga Khan University
Karachi
Pakistan

1. Introduction

In this chapter, we are presenting the review of the acid base disorders. The emphasis is on the pathophysiology and the underlying concepts. The complicated formulas and graphs are avoided and things are explained in the simple language. The basic acid base disorders namely metabolic acidosis, metabolic alkalosis, respiratory acidosis and respiratory alkalosis are discussed in detail. When appropriate the information is presented in the table forms to make it clear. Important references are also given for the interested readers.

2. Basic concepts

2.1 Acid and base

According to the standard definitions, acid is a substance which can donate H+ ion and base is a substance which can accept H+ ion (Ali, 1994; Boron, 2006; Kellum, 2007). Acids are of two types.

1. Volatile acids for example carbon dioxide (CO₂) which is regulated by the alveolar ventilation in the lungs.
2. Non-volatile acids for example lactic acid, sulfuric acid, phosphoric acid, uric acid and, keto acid. These acids may not be converted to CO₂ and hence must be removed from the body by the kidneys to keep the acid base in balance.

Acids and bases are also categorized according to their chemical behavior in the blood. They are called strong and weak. The strong acids and bases are completely ionized at the pH of 7.4. The weak acids and bases are ionized only partially at the pH of 7.4, depending upon their dissociation constant (pKa). Hydrochloric Acid (HCl) is a strong acid and Sodium Hydroxide (NaOH) is a strong base. Sodium Bicarbonate (Na HCO₃) is a weak acid (Boron, 2006; DuBose & Hamm, 1999; Kellum, 2007).

2.1.1 Acidemia

Acidemia is defined as an increase in H+ concentration of the blood. Acidemia may also be defined as a decrease in arterial pH.
2.1.2 Alkalemia
Alkalemia is defined as a decrease in the $H^+$ concentration of the blood. Alkalemia may also be defined as an increase in arterial pH.

2.2 Normal concentrations
The normal concentration of $H^+$ in plasma or serum is 40 nmol/liter and it varies inversely with the $HCO_3^-$ concentration.
The pH (Plasma concentration of $H^+$) is the negative log of $H$ concentration. Thus,
$$\text{pH} = - \log (H^+)$$
The normal arterial pH is 7.40, normal partial pressure of carbon dioxide ($PCO_2$) is 40 mmHg. Normal serum bicarbonate ($HCO_3^-$) concentration is 24 mEq/L.

Concentration of ions in a solution should be written in brackets. For example, for hydrogen ions as ($H^+$). However for the convenience it is often written with out brackets.

When coagulation factors are removed from the plasma, it is called serum. For practical purposes, plasma and serum are the same as far as the clinical medicine is concerned (DuBose & Hamm, 1999).

2.3 Buffers
Buffers are weak acids, i.e. they do not dissociate completely at the pH of 7.4. They accept or donate $H^+$ ions to prevent large changes in the free $H^+$ ion concentration.
The body buffers are divided into 3 groups:
(1) Extracellular (2) intracellular, and (3) bone

2.3.1 Extracellular buffers
Bicarbonate is the most important extracellular buffer due to its high concentration and also due to its ability to control the $PCO_2$ by alveolar ventilation. This system plays a central role in the maintenance of acid-base balance. $HCO_3^-$ is regulated by renal $H^+$ excretion and $PCO_2$ by the ventilation of lungs. Clinically, the acid base status of a person is expressed in terms of the principal extracellular buffer, the bicarbonate/$CO_2$ system.

Relationship between acid and base is expressed by the following equation:
$$(H^+) = 24 \times CO_2^+ (HCO_3^-)$$

Henderson-Hasselbalch equation is the modified form of the above simpler equation:
Henderson-Hasselbalch equation:
$$\text{pH} = 6.10 + \log (HCO_3^-) + (0.03 \times PCO_2)$$

pH is $-\log (H^+)$, 6.10 is the pKa, 0.03 is solubility constant for $CO_2$ in the extracellular fluid, and $PCO_2$ is the partial pressure of carbon dioxide in the extracellular fluid.

Other, less important buffers in the extracellular fluid are phosphates and the plasma proteins.

2.3.2 Intracellular buffers
The intracellular buffers are phosphates, hemoglobin ($Hgb$), and proteins.
2.3.3 Bone
It is an important buffer for acid and base loads with as much as 40 percent contribution in buffering (Halperin & Goldstein, 2002; Kellum, 2005).

3. Types of acid base disorders
There are four types of acid base disorders. A patient may present with one (simple) or more than one (mixed) disorder.
- Metabolic Acidosis
- Metabolic Alkalosis
- Respiratory Acidosis
- Respiratory Alkalosis

3.1 Acidosis
Acidosis is a process which tends to raise the hydrogen ion (H+) concentration.

3.1.1 Metabolic acidosis
When the process of acidosis is primarily due to retention of non volatile acid or due to bicarbonate loss, it is called metabolic acidosis. The arterial pH is low as well as serum bicarbonate concentration (Kraut & Madias, 2010).

3.1.2 Respiratory acidosis
When the process of acidosis is primarily due to CO2 retention, it is called respiratory acidosis. The arterial pH is low and PCO2 is high (Corey, 2005).

3.2 Alkalosis
Alkalosis is a process which tends to lower the hydrogen (H+) concentration.

3.2.1 Metabolic alkalosis
When the process of alkalosis is primarily due to loss of non volatile acid or due to retention of bicarbonate, it is called metabolic alkalosis. The arterial pH is high as well as serum bicarbonate concentration (Corey, 2005).

3.2.2 Respiratory alkalosis
When the process of alkalosis is primarily due to CO2 loss, it is called respiratory alkalosis. The arterial pH is high and PCO2 is low.

Acidosis and alkalosis are the processes. Acidemia and alkalemia are the end result of these processes. Acidosis induces acidemia and alkalosis induces alkalemia. In the body, these processes of acidosis and alkalosis never stop and one should use the terms acidosis and alkalosis rather than acidemia and alkalemia.
3.3 Compensations
The body responds to acid and base disorders by changes to bring the pH towards normal value. In respiratory disorders, bicarbonate (HCO₃⁻) changes to compensate. In metabolic disorders, partial pressure of carbon dioxide (P CO₂) changes to compensate. It is worthy of note that compensation always occurs in the same direction as the primary disorder (Adrogue & Madias, 1998; Corey, 2005).

4. Acute and chronic
Respiratory acidosis and respiratory alkalosis are divided into two groups, acute and chronic, on the basis of their compensation. There are no plasma buffers for respiratory acidosis or alkalosis. The role of intracellular buffers and bone buffers is minor. The renal compensation takes about 3 to 5 days to complete. Hence the acute phase continues for 3 to 5 days. Once full renal compensation is in place, the respiratory acidosis and respiratory alkalosis are called chronic. On the other hand, metabolic acidosis and metabolic alkalosis are not divided into acute and chronic groups. However, sometimes the terms acute metabolic acidosis or alkalosis, and chronic metabolic acidosis or alkalosis are used. They indicate the time period, and not the compensatory response. In the metabolic disorders, the plasma buffers act immediately and respiratory compensation occurs quickly with in minutes to hours, so the acute phase, if any, is very brief (Schrier, 2003).

5. Diagnosis of acid base disorders
Evaluation of any acid-base disorder requires measurement of arterial blood gases (ABGs) and serum bicarbonate (HCO₃⁻) concentration. The Henderson-Hasselbalch equation shows that the pH is determined by the ratio of HCO₃⁻ concentration to P CO₂. In metabolic acidosis, the primary event is a drop in the serum HCO₃⁻ and P CO₂ drops as a secondary response. In respiratory alkalosis, the primary event is a drop in PCO₂ and bicarbonate drops as a secondary event. PCO₂ and HCO₃⁻ both will be low in metabolic acidosis as well as in respiratory alkalosis. The pH will be low in metabolic acidosis and high in respiratory alkalosis (Boron, 2006; Corey, 2005; DuBose & Hamm, 1999; Kellum, 2007; Lowenstein, 1993).

Similarly, PCO₂ and HCO₃⁻ will be high in metabolic alkalosis as well as in respiratory acidosis. The pH will be high in metabolic alkalosis and low in respiratory acidosis.

Table 1. Compensation in Simple Acid Base Disorders (Direction of primary and secondary event is always same)

The second step in the diagnosis of acid base disorders is to evaluate the degree of compensation. Once the disorder is diagnosed, the degree of compensation should be assessed. The expected degree of compensation is predefined on the basis of studies and experiments done by the scientists (Table 2).

Table 2. Expected Degree of Compensatory Responses

5.1 Metabolic acidosis
The diagnosis of a simple metabolic acidosis requires low serum bicarbonate and a low extracellular pH.

5.1.1 Mechanism of acid production
The pathophysiology is better understood if we classify the metabolic acidosis on the basis of the mechanisms of acid production (Table 3).

(1) Increased Acid (H<sup>+</sup>) Generation
In these disorders, there is either an increased H<sup>+</sup> generation due to deranged metabolism in the body or by the increased administration of chemicals which are the source of H<sup>+</sup> ions. Examples of the first are lactic acidosis, keto acidosis and examples of the later are methanol poisoning, ethylene glycol poisoning, and salicylate poisoning.

(2) Increased Loss of HCO<sub>3</sub>-
In these disorders, the primary event is loss of HCO<sub>3</sub>-, which in turn leaves behind H<sup>+</sup> ions. Examples are diarrhea, ureteral diversion, and proximal renal tubular acidosis (RTA type 2).

(3) Diminished Renal Acid (H<sup>+</sup>) Excretion
In these disorders, there is decreased excretion of acid (H<sup>+</sup>) from the kidneys. The kidneys are responsible for removing the daily non volatile acid load and to increase the H<sup>+</sup> excretion in case of metabolic acidosis. Obviously, when kidneys themselves are not competent, metabolic acidosis will occur. Examples of decreased acid (H<sup>+</sup>) excretion are renal failure, distal renal tubular acidosis (RTA type 1), and RTA type 4.
### Increased Acid (H+) Generation

- Lactic acidosis
- Ketoacidosis
- Methanol Poisoning
- Ethylene Glycol Poisoning
- Salicylate Poisoning

### Increased Loss Of \( \text{HCO}_3^- \)

- Diarrhea
- Ureteral diversion
- Proximal renal tubular acidosis (Type 2)

### Diminished Renal Acid (H+) Excretion

- Renal failure
- Distal renal tubular acidosis (type 1)
- Renal tubular acidosis type 4

Table 3. Important Causes of Metabolic Acidosis (According to the Mechanism)

#### 5.1.2 High and normal anion gap

Metabolic Acidosis may also be divided into two groups according to the serum anion gap.

1. **High Serum Anion Gap Metabolic Acidosis**
2. **Normal Serum Anion Gap Metabolic Acidosis** (Table 4)

The terms gap and non-gap metabolic acidosis are used sometimes. There is always an anion gap, normal, high, low, or negative. The gap/no gap terminologies should be abandoned.

Table 4. Important Causes of Metabolic Acidosis (According to the Serum Anion Gap)
Serum Anion Gap (Serum AG) is the difference between the routinely measured cations i.e. sodium (Na) and sum of routinely measured anions i.e. chloride (Cl) and bicarbonate (HCO$_3^-$). It can be calculated from the following formula:

$$\text{Serum AG} = \text{Routinely Measured Cations} - \text{Routinely Measured Anions}$$

$$\text{Serum AG} = \text{Na} - (\text{Cl} + \text{HCO}_3^-)$$

Although, serum potassium (K) is also routinely measured but it is omitted from calculations. The reasons for omission of K from calculation are twofold. First, its serum concentration range is small, and second, if it is changed drastically, patient will succumb to its consequences before the change in the anion gap is considered. The serum anion gap may also be written as following.

$$\text{Serum AG} = \text{Unmeasured anions} - \text{Unmeasured cations}$$

Unmeasured anions are albumin, lactate, sulfate, urate, phosphate, and other anions. Unmeasured cations are potassium, magnesium, calcium, and other cations. Serum AG will increase when there is a rise in the unmeasured anions or fall in the unmeasured cations. The serum anion gap (AG) will not increase if the H$^+$ ion is accompanied by chloride. Serum AG will increase if acid H$^+$ accompanies an anion other than chloride. The normal range of the serum AG is 10± 3 meq/L. Negatively charged serum albumin contributes most of the serum AG. One g/dL of serum albumin is equal to 2.5 meq/L of anion gap.

Examples of normal AG metabolic acidosis are diarrhea and RTA.
Examples of high AG metabolic acidosis are lactic acidosis, keto acidosis, renal failure, methanol poisoning, and ethylene glycol poisoning (Corey, 2005; Emmett & Narins, 1997; Fidkowski & Helstrom, 2009).

5.1.3 Delta anion gap/delta bicarbonate
The ratio of increase in serum Anion Gap to decrease in plasma bicarbonate is called Delta AG (Δ AG)/Delta HCO$_3$ (Δ HCO$_3$) ratio, or just Δ/Δ ratio. It is a useful tool in sorting out the cause of metabolic acidosis. In case of high anion gap metabolic acidosis, the drop in HCO$_3^-$ should match the rise in the AG. In other words, the Δ/Δ ratio should be 1:1. In lactic acidosis, AG increases more than the drop in serum HCO$_3^-$ and Δ/Δ ratio may be as high as 1.6:1. The reason for this discrepancy is buffering of the part of the H$^+$ by the intracellular and bone buffers. The part of the H$^+$ which is taken care by the intracellular and bone buffers does not lower the serum HCO$_3^-$ concentration. The accompanied anion (lactate) remains in the extracellular fluid and raises the AG. In ketoacidosis, the Δ AG/Δ HCO$_3$ ratio is usually 1:1 due to partial excretion of ketones from the kidneys which balance out the intracellular and bone buffering. In mixed high anion gap and normal anion gap metabolic acidosis, the Δ AG/Δ HCO$_3$ ratio will be less than one (Fidkowski & Helstrom, 2009; Kellum, 2007; Rastegar, 2007). In mixed metabolic alkadosis and metabolic acidosis, the Δ AG/Δ HCO$_3$ ratio will be more than 2. It this case, the drop in HCO$_3^-$ is much less than the rise in AG due to concomitant metabolic alkalosis.
In the following paragraphs urinary anion gap, urinary osmolar gap, and serum osmolar gap are explained. These are the commonly used investigations in solving the complicated acid base disorders.

5.1.4 Urinary anion gap
The urinary anion gap is the difference between major urinary cations (sodium and potassium) and major urinary anions (chloride). It is calculated as follows:

\[ \text{Urinary Anion Gap} = (\text{Na} + \text{K}) - (\text{Cl}) \]

Urinary AG is an indirect measurement of urinary ammonium (NH\text{+4}) excretion. Negative value means chloride concentration of urine is higher than the sum of sodium and potassium. Negative urine AG is an appropriate response to metabolic acidosis. An increased NH\text{+4} excretion results in enhanced acid removal from the kidney, for example, in diarrhea (DuBose TD Jr, et al. 1991; Oh & Carrol, 2002; Rose et al., 2001; Schoolwerth, 1991). Positive value means chloride concentration of urine is less than the sum of sodium and potassium. Positive urine anion gap indicates decreased NH\text{+4} excretion, and decreased acid removal from the kidney, for example in renal tubular acidosis (Batlle et al., 1988).

5.1.5 Urinary osmolar gap
Just like urinary AG the urine osmolar gap (UAG) is a measure of urinary NH\text{+4} excretion. An advantage of urine osmolar gap is that, it is not dependent on urinary chloride. It takes account of all the urinary anions accompanied with ammonium. It is calculated as follows:

\[ \text{Urinary Osmolar Gap} = \text{Measured urine osmolality} - \text{Calculated urine osmolality} \]

\[ \text{Calculated urine osmolality} = 2 \times (\text{Na} + \text{K}) + \text{Urine Urea Nitrogen} + \text{Urine Glucose} \]

\[ \text{2.8} \]

In the above formula, 2 indicates the anions accompanying sodium and potassium. Na and K are in meq/L , Urea Nitrogen and glucose are in mg / dl. (Kamel et al., 1990).

5.1.6 Serum osmolar gap
It is the difference between measured serum osmolality and calculated serum osmolality. Measured serum osmolality includes all the serum osmoles. Calculated osmolality includes only some selected ones (Kamel et al., 1990).

\[ \text{Calculated Serum Osmolality} = 2 \times \text{Na} + \text{Blood Urea Nitrogen mg/dl} + \text{Blood Glucose mg/dl} \]

\[ \text{2.8} \]

In the above formulas, 2 indicates the anions accompanying sodium. Normal serum osmolar gap is about 5 to 10. Examples of high osmolar gap metabolic acidosis are methanol and ethylene glycol intoxication. There are conditions when serum osmolar gap is high with out acidosis, eg. mannitol infusion and ethanol ingestion (Lynd et al., 2008).
6. Stewart approach

Traditionally, the hydrogen ion concentration (pH) of blood is expressed as a function of the ratio of PCO₂ and serum HCO₃⁻ based upon Henderson-Hasselbalch equation. An alternative approach was proposed by Stewart, which is called Stewart’s approach or strong ion difference (SID) approach. The SID is the difference between the concentration of strong cations and concentration of strong anions in the plasma. Major strong cations are Na⁺, K⁺, Ca²⁺, Mg²⁺, and the major strong anions are Cl⁻ and lactate⁻. According to SID approach, there are six primary acid-base disturbances. These are respiratory acidosis, respiratory alkalosis, strong ion acidosis, strong ion alkalosis, nonvolatile buffer ion acidosis, and nonvolatile buffer ion alkalosis. Stewart proposed that the serum bicarbonate concentration is not independent and does not play an active role in the determination of the H⁺ concentration. According to Stewart’s theory of SID, the plasma concentrations of nonvolatile weak acids and PCO₂ are independent variables. Nonvolatile total weak acids are phosphate and charges of albumin. The pH depends upon these three variables and not on HCO₃⁻/PCO₂ ratio. The SID method was presented by Stewart as an alternative to serum AG method for solving the acid-base problems. However, it did not get the popularity. Many physiologists believe that Stewart’s method does not give any additional information if serum AG is corrected for serum albumin concentration (Fidkowski & Helstrom, 2009; Kellum et al., 1995).

7. Modified base excess method

Base excess is the amount of acid or base that must be added to the solution to bring the pH to 7.4 at PCO₂ of 40 mmHg and temperature of 37°C. Negative base excess means there is acidemia and positive base excess means there is alkalemia. The modified or sometimes called “standardized base excess method” is based upon Stewart’s theory. It may be defined as the amount of strong acid or strong base required to bring the pH to 7.4 and PCO₂ to 40 mmHg (Fidkowski & Helstrom, 2009; Kraut & Madias, 2007; Rastegar, 2009). Arterial Blood Gas machine gives a calculated base excess value. Any therapeutic decision cannot be taken on this calculated value because of two reasons. First, it may give a false value of zero when metabolic acidosis and metabolic alkalosis coexist. Second, it is impossible to predict the PCO₂ level and pH after correcting the base excess or deficit. This standardized base excess method does not give any advantage over traditional Henderson-Hasselbalch equation based methods. In the following paragraphs important causes of metabolic acidosis are discussed.

8. Chronic and acute renal failure

The new name for chronic renal failure is chronic kidney disease and the new name for acute renal failure is acute kidney injury. Metabolic acidosis in renal failure results from reduced number of functioning nephrons. The single nephron function is intact. The initial stages of renal dysfunction give rise to normal anion gap and later stages give rise to high anion gap metabolic acidosis. The anions accompanying the acid are sulfate, phosphate and urates. In early stages of renal failure, these anions are excreted without problem; thus the anion gap remains normal.
In latter stages of renal failure, there is retention of these unmeasured anions and high anion gap metabolic acidosis develops (Kraut & Kurtz, 2005; Narins & Emmett, 1980).

### 9. Methanol and ethylene glycol intoxication

Methanol and ethylene glycol are ingested for pleasure as a substitute for ethanol, and also in the suicidal attempts, or taken accidently. Moonshine is a nickname of methanol when it is made illegally or locally using the radiators of the motor vehicles. Antifreeze solution contains high concentration of ethylene glycol (Lynd et al., 2008).

#### 9.1 Methanol

Methanol is oxidized to formate by alcohol dehydrogenase and aldehyde dehydrogenase. Formate causes retinal injury with optic disc edema, blindness which may be permanent and basal ganglia injury.

High anion gap metabolic acidosis develops due to accumulation of formate (formic acid). Serum AG is increased. (Kraut & Kurtz, 2008). Serum osmolar gap is increased.

#### 9.2 Ethylene Glycol

Ethylene Glycol is metabolized to glycolate (glycolic acid), oxalate (oxalic acid), and glyoxylate by alcohol dehydrogenase and aldehyde dehydrogenase. Renal failure occurs due to renal tubular damage by glycolic acid and precipitation of oxalate crystals in the kidneys. High anion gap metabolic acidosis develops due to accumulation of glycolic acid and oxalic acid. Serum AG is increased. (Kraut & Kurtz, 2008). Serum osmolar gap is increased.

### 10. Lactic acidosis

Lactic acidosis is one of the most common causes of metabolic acidosis. Lactic acid is derived from the metabolism of pyruvic acid, which is generated from glucose and amino acids. Increased anaerobic metabolism lead to increased lactate production. The lactate produced in lactic acidosis is L-Lactate type, the accumulation of which gives rise to high anion gap.

The causes of lactic acidosis can be divided into type A, and type B. Type A lactic acidosis is associated with obviously impaired tissue oxygenation, for example, in shock, sepsis, hypovolemia, and cardiac failure.

In type B lactic acidosis, the impairment in oxygenation is not apparent. There is mitochondrial dysfunction due to toxins and drugs like metformin and nucleoside reverse transcriptase inhibitors (NRTIs).

#### 10.1 D-lactic acidosis

D-lactate is produced in the colon from metabolism of starch and glucose by the gram-positive anaerobes. In the setting of short bowel syndrome and malignancy, over production of D-lactate with severe metabolic acidosis may occur. Diagnosis may be difficult because the usual assays used in laboratories detect only L-lactate.

### 11. Ketoacidosis

Ketoacids are derived from metabolism of fatty acids in the liver. Normal metabolism of fatty acids give rise to formation of triglycerides, CO₂, water, and ketoacids. However in the absence of insulin, ketoacids are produced out of proportion and cause acidosis.
Ketoacids are; (1) $\beta$-Hydroxy butyric acid, and (2) Acetoacetic acid. Acetone is often grouped with Ketoacids but it is not an acid. Uncontrolled Diabetes Mellitus is the most common cause of Ketoacidosis. Starvation and excessive alcohol intake may also give rise to mild to moderate ketoacidosis. Diagnosis of Ketoacidosis requires documentation of Ketones in the blood or urine (Arieff & Carroll, 1972).

12. Dilutional metabolic acidosis
It is due to a fall in the serum bicarbonate concentration secondary to extracellular volume expansion by nonbicarbonate fluid. Massive amounts of normal saline infusion may produce dilutional acidosis. It is not a clinically significant entity and only of academic interest.

13. Salicylate poisoning
Aspirin (acetyl salicylic acid) poisoning results in mixed respiratory alkalosis and metabolic acidosis. Metabolic acidosis is due to accumulation of salicylic acid as well as lactic acid and ketoacids. Liver plays an important role in the detoxification of salicylate. In case of overdose, this system of detoxification saturates and results in deposition of salicylates in the tissues including brain.

14. Renal Tubular Acidosis (RTA)
There are 3 types of RTA:
Distal RTA (type 1)
Proximal RTA (type 2)
Hyporenin hypoaldosteronism (RTA type 4)
There is a Type 3 RTA also which is a rare autosomal recessive disorder due to carbonic anhydrase II deficiency and has features of both distal and proximal RTA (Table 5).

Table 5. Comparison of Renal Tubular Acidosis
14.1 Distal RTA (type 1)
In distal RTA, the main problem is impaired secretion of acid (H\(^+\)) from the intercalated cells of the collecting tubules. Collecting tubules has two types of cells: (1) principal cells, which are responsible for sodium and potassium balance, and (2) intercalated cells which are responsible for (H\(^+\)) secretion and maintenance of acid base balance. As a result of decreased H\(^+\) secretion, there is decreased ammonium (NH\(_4^+\)) and decreased titratable acid excretion. Titratable acid means the acid removed by phosphate buffer system of urine. Anion Gap is normal because of retention of chloride along with H\(^+\) ions. Nephrocalcinosis and nephrolithiasis are known complication of RTA type 1. High urine pH facilitates calcium phosphate precipitation and stone formation in the renal tubules and urinary collecting system (Batlle et al., 2006; Karet, 2009; Rodríguez, 2002).

14.2 Proximal RTA (type 2)
In RTA type 2, the proximal bicarbonate (HCO\(_3^-\)) reabsorption threshold is reduced and this results in the loss of filtered HCO\(_3^-\). Once a new steady state is achieved with low serum HCO\(_3^-\) the loss of bicarbonates ceases. Urine pH is initially high due to bicarbonaturia and later may drop to less than 5.3 in untreated persons.

14.3 Type 4 RTA
In type 4 RTA, the primary defect is decreased potassium (K) secretion from the distal nephron, mainly collecting tubules due to aldosterone deficiency or resistance. The decreased H\(^+\) secretion and subsequent metabolic acidosis is secondary to defective K secretion. Most common cause of Type 4 RTA is hyporenin hypoaldosteronism syndrome. A decreased K secretion results in hyperkalemia and its treatment improves metabolic acidosis (Rodríguez, 2002).

15. Metabolic alkalosis
There are two stages of metabolic alkalosis: (1) Generation of alkalosis, and (2) Maintenance of alkalosis. The kidneys are very efficient in correcting the metabolic alkalosis by excreting out the extra bicarbonate. Only generation of alkalosis is not sufficient to produce alkalemia. There must be some other factors present to maintain the alkalosis. Hypovolemia and hypochloremia are the most important etiologies responsible for maintenance of alkalosis (Table 6 and 7) (Khanna & Kurtzman, 2006).

15.1 Urine chloride
Measurement of urine chloride concentration is a key test used in solving the differential diagnosis of metabolic alkalosis. It differentiates between hypovolemic and euvoletic states. In metabolic alkalosis, urine chloride is more reliable indicator of volume status as compared to urine sodium. Urine sodium may be high in spite of hypovolemia in metabolic alkalosis. It is due to the obligatory loss of sodium along with bicarbonate spill over. Based upon urine chloride concentration, the causes of metabolic alkalosis may be divided in two groups (Table 8).

15.2 Saline responsiveness
Metabolic alkalosis may also be classified according to the response to saline administration. Urine chloride will be low in saline responsive alkalosis. Urine chloride may be high or low in saline resistant alkalosis.
Renal Loss of Acid ($H^+$)
- Diuretics
- Hypermineralcoricoidosis
- Post Hypercapnia

Gastrointestinal Loss of Acid ($H^+$)
- Vomiting
- Nasogastric Suction
- Chloride Loosing Diarrhea

Addition of Bicarbonate
- Administration of Sodium Bicarbonate
- Blood transfusion
- Milk Alkali Syndrome

Trans cellular Shift
- Hypokalemia

Excessive Hypotonic Fluid Loss
- Contraction Alkalosis

Table 8. Causes of Metabolic Alkalosis

15.3 Saline responsive
In these conditions, correction of hypovolemia will result in increased delivery of chloride and sodium to the distal nephron which will result in increased sodium bicarbonate excretion. Examples: Vomiting, Nasogastric Suction, Diuretics, Posthypercapnia.
15.4 Saline resistant
In these conditions, the specific treatment of underlying cause is required to correct the alkalosis. Edematous states may respond to saline but may develop pulmonary edema and worsening of peripheral edema.
Examples: Congestive heart failure, Cirrhosis, Mineralocorticoid excess, Hypokalemia and Renal Failure.
Pathophysiology of the important causes of metabolic alkalosis is discussed below.

15.5 Gastrointestinal losses
The secretion of bicarbonate from the pancreas depends upon stimuli by the acid coming from stomach to the duodenum. Vomiting or nasogastric tube drainage prevents the acid from reaching the duodenum resulting in the decreased secretion of bicarbonate. The hydrochloric acid (HCl) loss and retention of bicarbonate results in metabolic alkalosis.

15.6 Diuretics
The loop diuretics are the common cause of metabolic alkalosis. They produce alkalosis by volume contraction, increased urinary H⁺ loss and hypokalemia.

15.7 Hyperaldosteronism
Primary and secondary mineralocorticoid excess results in metabolic alkalosis. It is primarily due to increased acid secretion from the distal nephron.

15.8 Post hypercapnic alkalosis
Rapid lowering of the blood carbon dioxide (CO₂) in chronic CO₂ retainers will cause post hypercapnic metabolic alkalosis. Chronic retention of CO₂ stimulates renal HCO₃ retention to compensate for respiratory acidosis. Once CO₂ content of the blood is reduced quickly, for example, by ventilator, the compensated HCO₃ component is unmasked resulting in metabolic alkalosis.

15.9 Milk alkali syndrome
Excessive intake of calcium salts, for example calcium carbonate, may result in metabolic alkalosis, especially in renal failure. Carbonate is converted to HCO₃ in the body and calcium decreases HCO₃ excretion from the kidneys. It is called milk alkali syndrome because of its association with milk intake which contains large amounts of calcium.

15.10 Hypokalemia
Decreased plasma potassium (K⁺) level causes shift of K⁺ from intracellular to extra cellular fluid, in an attempt to correct hypokalemia. To keep the electrical neutrality, H⁺ shifts from outside to the inside of the cells. This loss of H⁺ from extracellular fluid results in metabolic alkalosis.
It is interesting to note that metabolic alkalosis itself perpetuates hypokalemia. In metabolic alkalosis of any cause, transcellular shift of H⁺ and K⁺ takes place. H⁺ ions move out of the cells to correct alkalosis and K⁺ moves inside the cells producing hypokalemia.

15.11 Bicarbonate administration
As mentioned above, in euvoletic persons with normal renal function, it is impossible to produce alkalosis due to rapid renal excretion of any administered HCO₃. However, in
hypovolemia or in renal failure, administration of bicarbonates results in metabolic alkalosis simply due to inability of the kidneys to excrete the extra bicarbonates.

15.12 **Multiple blood transfusions**
Massive blood transfusion occasionally results in metabolic alkalosis. Citrate which is used as an anticoagulant in blood is converted to bicarbonate in the liver resulting in metabolic alkalosis.

15.13 **Contraction alkalosis**
Loss of water around a fixed amount of HCO$_3^-$ results in increased concentration of HCO$_3^-$ and metabolic alkalosis. The increased pure water loss and hypotonic fluid loss by loop diuretics, excessive sweating and congenital chloride diarrhea are examples of conditions associated with contraction alkalosis.

15.14 **Bartter’s syndrome and Gitelman’s syndrome**
These are the autosomal recessive disorders characterized by hypokalemia and metabolic alkalosis.
In Bartter’s syndrome, there is a defect in the sodium chloride transport in the thick ascending limb of the loop of Henle at the site of action of loop diuretics. The characteristic abnormalities include hypokalemia, metabolic alkalosis and increased urinary calcium excretion.
In Gitelman’s syndrome, there is a defect in the sodium chloride transport in the distal tubule which is the site of action of thiazide diuretics. The characteristic abnormalities include hypokalemia, metabolic alkalosis, decreased urinary calcium excretion, and hypomagnesaemia.

16. **Respiratory acidosis and alkalosis**

16.1 **Respiratory acidosis**
The primary event in respiratory acidosis is retention of CO$_2$. Metabolism of carbohydrates and fats results in the production of CO$_2$ which combines with H$_2$O to form H$_2$HCO$_3$. It then dissociate into acid (H$^+$) and bicarbonate (HCO$_3^-$).

\[
\text{CO}_2 \times 0.03 + \text{H}_2\text{O} \leftrightarrow \text{H}_2\text{HCO}_3 \leftrightarrow \text{HCO}_3^- + \text{H}^+
\]

Kidneys compensate to respiratory acidosis by increasing acid (H$^+$) excretion.
Lungs through alveolar ventilation remove CO$_2$. In the absence of ventilation, CO$_2$ will accumulate in the body and will result in severe acidosis (rise of free H$^+$ ions and drop of pH). This type of acidosis is called respiratory acidosis (Arieff & Carroll, 1972).
According to the Henderson-Hasselbalch equation, pH depends upon the ratio of bicarbonate and PCO$_2$

\[
\left[\text{H}^+\right] = 24 \times \frac{\text{PCO}_2}{\text{HCO}_3^-}
\]

\[
\text{pH} = 6.10 + \log \frac{\text{HCO}_3^-}{0.03 \text{ PCO}_2}
\]
The partial pressure of CO$_2$ (PCO$_2$) in the arterial blood is in equilibrium with that in the alveolar air. Normal arterial PCO$_2$ is approximately 40 mmHg. CO$_2$ is not an acid. It increases the acidity of the solution through the formation of H$_2$CO$_3$. Increased PCO$_2$ will increases the H$_2$CO$_3$ concentration. It then dissociates into the acid (H$^+$) and bicarbonate (HCO$_3^-$). In contrast to metabolic acidosis, bicarbonate (HCO$_3^-$) does not act as a buffer in respiratory acidosis. It is part of the problem, not part of the solution. Sodium bicarbonate administration in respiratory acidosis is not beneficial, rather may be harmful. Administration of bicarbonate will result in an initial transient rise in pH due to the left shift. Then, H$_2$CO$_3$ will immediately dissociate and the net result will be higher PCO$_2$, higher HCO$_3^-$, higher H$^+$, and lower pH. Intracellular buffers mostly hemoglobin (Hgb) bind free H$^+$ and form H$^+-$Hgb which is carried to lungs by the blood circulation. In the lungs, H$^+$ is released form Hgb and combines with available HCO$_3^-$ to form CO$_2$, which is exhaled by lungs to the atmosphere. Increasing ventilation is the only treatment of respiratory acidosis. Renal response to increased H$^+$ excretion takes about 3 to 5 days to complete. At this stage, the respiratory acidosis is termed chronic. The PCO$_2$/HCO$_3^-$ ratio improves to settle pH at a higher level than it was in acute phase. This renal compensation is always suboptimal. If the pH is 7.4 or above, it means that there is a concomitant component of metabolic alkalosis. The degree of compensation and expected pH after compensation are predefined (Table 2).

16.1.1 Causes of respiratory acidosis
The cause of respiratory acidosis is only one, that is, decreased ventilation. Several conditions can lead to decreased ventilation and respiratory acidosis. Causes of decreased ventilation may be divided into three groups. Important ones are listed here:
Central: Norcotics, Sedatives, Anaesthesia,
Peripheral: Neuropathies, Muscle weakness, Myopathies
Pulmonary and Airway Pathology: Pneumnia, Pneumothorax, Sleep apnea, and Emphysema.

16.2 Respiratory alkalosis
The primary event in respiratory alkalosis is decreased PCO$_2$. According to the Henderson-Hasselbalch equation, pH depends upon the ratio of bicarbonate and PCO$_2$ as mentioned above. Lower the PCO$_2$ the higher the pH and vice versa. Extracellular buffers are not efficient in respiratory alkalosis. Intracellular buffers e.g. protein, phosphate and Hgb act to release intracellular H$^+$ in an attempt to correct the alkalosis. This response also is not very efficient. Renal response of decreasing H$^+$ secretion takes 3 to 5 days to complete. At this stage, it is called chronic respiratory alkalosis.

16.2.1 Causes of respiratory alkalosis
Like respiratory acidosis, the cause of respiratory alkalosis is only one, that is, increased ventilation. Important causes of increased ventilation are listed here:
Hypoxemia, Sepsis, Salicylate intoxication, Pregnancy, stroke, Liver Failure, Psychological Causes, Artificial by ventilator (Kaplan & Frangos, 2005).

17. Conclusion
Primary acid base disorders are metabolic acidosis, metabolic alkalosis, respiratory acidosis, and respiratory alkalosis. In practice, patients often present with mixed and complex acid
base problems. Understanding the underlying pathophysiology is the best way of reaching at the correct diagnosis. The various formulae are helpful but are not substitute to the clear concepts.

Lowenstein. Acids and Basics. New York University, 1993

www.intechopen.com
There is no dearth of high-quality books on renal biopsy and pathology in the market. These are either single author or multi-author books, written by world authorities in their respective areas, mostly from the developed world. The vast scholarly potential of authors in the developing countries remains underutilized. Most of the books share the classical monotony of the topics or subjects covered in the book. The current book is a unique adventure in that it bears a truly international outlook and incorporates a variety of topics, which make the book a very interesting project. The authors of the present book hail not only from the developed world, but also many developing countries. The authors belong not only to US but also to Europe as well as to Pakistan and Japan. The scientific content of the book is equally varied, spanning the spectrum of technical issues of biopsy procurement, to pathological examination, to individual disease entities, renal graft pathology, pathophysiology of renal disorders, to practice guidelines.
