1. Introduction

Hepatic encephalopathy (HE) reflects a spectrum of neuropsychiatric abnormalities seen in patients with liver dysfunction after exclusion of other known brain disease.

Classification of hepatic encephalopathy is based on the clinical setting in which symptoms occur (Table 1). The encephalopathy of acute liver failure shares clinical characteristics with that of cirrhosis, but also exhibits unique features. In cirrhosis, three major syndromes can be present:

1. Episodic (precipitant-induced) encephalopathy, commonly seen in the hospital setting, where a superimposed event is a key factor.
2. Persistent (chronic) encephalopathy, seen with extensive portal-systemic shunts and after portocaval shunt surgery or placement of transjugular intrahepatic portosystemic shunt (TIPS).
3. Minimal (subclinical) encephalopathy reflects alterations in cognitive function in patients who clinically exhibit a normal mental state.

TIPS, transjugular intrahepatic portosystemic shunt.

Table 1. Classification of hepatic encephalopathy.
Minimal hepatic encephalopathy (MHE), the mildest form of HE, is characterized by subtle motor and cognitive deficits, and impairs health-related quality of life (HRQOL).\textsuperscript{2}

Cirrhotic patients with MHE have a normal neurological and mental status by the standards of clinical examination, yet demonstrate quantifiable neuropsychological defects.\textsuperscript{3} The term MHE refers to the subtle changes in cognitive function, electrophysiological parameters, cerebral neurochemical/neurotransmitter homeostasis, cerebral blood flow, metabolism, and fluid homeostasis that can be observed in patients with cirrhosis who have no clinical evidence of hepatic encephalopathy.\textsuperscript{4}

MHE has been described previously using several different names, such as, early, low-grade, latent or subclinical HE to identify patients with subtle cognitive function abnormalities.

These subtle neurocognitive abnormalities primarily affect attention, speed of information processing, and motor abilities and coordination that are not recognizable on standard neurological examination. These neurocognitive abnormalities are independent of sleep dysfunction or problems with overall intelligence.\textsuperscript{5-8}

It has been well-described that MHE has a subtle but negative impact on a patient’s spatial skills, motor skills, the ability to perform complex tasks such as driving, and even quality of life.\textsuperscript{3-5} MHE predicts the development of overt HE and is associated with poor survival.\textsuperscript{2} Its negative impact on daily living, among other reasons, has led some authors to suggest that the failure to diagnose this condition could be classified as a medical error.\textsuperscript{9,10}

2. Epidemiology

There are no accurate data on the incidence of HE. HE is classified as: overt hepatic encephalopathy (OHE) and MHE.

OHE occurs in 30\% to 45\% of cirrhotic patients\textsuperscript{11} and in 10\% to 50\% of patients with TIPS\textsuperscript{12} and can be clinically diagnosed.

The true prevalence of MHE in patients with portal hypertension is inunknown. MHE has been diagnosed in patients with liver cirrhosis and in patients with noncirrhotic portal hypertension. The prevalence of MHE has been reported in as many as 20\%-84\% of cirrhotics, depending on which methods or tools are used and fixed diagnostic cut-offs.\textsuperscript{2,3} Large variations in the prevalence of MHE are related to prior episode of OHE, severity of liver disease, age, presence of esophageal varices, and surgical porto-systemic shunts. Patients who develop MHE are older, more often have alcohol as etiology of cirrhosis, have history of overt HE in the past, have more severe liver disease, and more often have esophagogastric varices.\textsuperscript{2,13}

3. Pathogenesis

Despite much scientific research, the exact pathophysiological mechanisms leading to HE are not clearly understood. The most widely accepted theory of the pathogenesis of HE is that nitrogenous substances derived from the gut adversely affect the cerebral function.
3.1 Ammonia

There are various explanations why liver dysfunction or portosystemic shunting might lead to encephalopathy. In healthy subjects, intestinal neurotoxins, such as ammonia, manganase and the benzodiazepine-GABA system generated by gut bacteria from food, are transported by the portal vein to the liver, where 80–90% is metabolized and/or excreted immediately. In all subtypes of hepatic encephalopathy this process is impaired, either because the hepatocytes are incapable of metabolizing the neurotoxins or because portal venous blood bypasses the liver through collateral circulation or a medically constructed shunt. Neurotoxins accumulate in the systemic circulation. Ammonia plays a key role in the pathogenesis of HE. The small molecules of ammonia cross the blood–brain barrier and are absorbed and metabolized by astrocytes, population of cells in the brain that constitutes 30% of the cerebral cortex. Alzheimer type II astrocytes are the only cells containing glutamine synthetase that metabolize ammonia. It is hypothesized that glutamine synthesis within the astrocytes causes brain swelling. Astrocytes also provide physical and nutritional support for neurons, maintain the integrity of the blood–brain barrier and regulate cerebral blood flow.

Ammonia also modulates glutamate neurotransmission and induces neurosteroid production in neurons, leading to a positive modulatory effect on the gamma-aminobutyric acid-A receptor. The precise molecular mechanism(s) responsible for neurological alteration in HE are not known. HE is associated with alterations in the expression of astrocytic and neuronal genes that code for various proteins that play a critical role in central nervous system function including maintenance of cell volume and neurotransmission.

The pathogenesis of MHE is similar to that of HE. An increase in brain glutamine and brain water is pathophysiological change associated with deterioration in neuropsychological performance. Alterations in cerebral blood flow and glucose metabolism induced by ammonia are associated with a significant decrease of glucose utilization by various cortical regions that are involved in cognitive functions. The cerebral metabolic rate for ammonia and the permeability-surface area product for ammonia are significantly higher in patients with MHE. The increased permeability-surface area product of the blood–brain barrier permits ammonia to diffuse across the blood–brain barrier into the brain more freely than normal. This may cause ammonia-induced encephalopathy even though arterial ammonia levels are normal or near normal.

Cognitive deficits observed in patients with noncirrhotic portal hypertension have also been linked to ammonia. Patients with noncirrhotic portal hypertension, such as extrahepatic portal venous obstruction, exhibited abnormalities in the results of neuropsychological tests, oral glutamine challenge test, and magnetic resonance (MR) imaging and spectroscopy similar to those described in HE associated with cirrhosis.

Other waste products implicated in hepatic encephalopathy include mercaptans (substances containing a thiol group), short-chain fatty acids and phenol.

3.2 Serotonin

Serotonin, a neurotransmitter with widespread distribution in the CNS, is important for the regulation of sleep, circadian rhythmicity and locomotion. Changes in the synthesis, metabolism, storage and release of neuronal serotonin in HE suggest a serotonergic synaptic
deficit. Serotonin metabolism is exquisitely and selectively sensitive to the degree of portosystemic shunting and hyperammonaemia, suggesting a role for serotonin in early neuropsychiatric symptoms of HE.  

3.3 Branched-chain amino acids (BCAA) and false neurotransmitters

An imbalans between aromatic aminocoacids (AAA) (phenylalanine, tryptophan and tyrosine) and branched-chain amino acids (BCAA) (leucine, isoleucine and valine) has been described in patients with severe liver dysfunction. AAA and BCAA share a common transport mechanism into the CNS. AS a consequence of increased concentration of AAA, neuronal levels may be raised leading to the production of false neurotransmitters (octopamide and phenylethanolamide) with subsequent development of HE.

3.4 Zink

Zinc is a substrate of urea cycle enzymes. It may be depleted in patients with cirrhosis. Zinc supplementation increases the activity of ornithine transcarbamylase increasing excretion of ammonia ions. There is conflicting clinical data regarding zinc supplementation in the management of HE.

3.5 Manganese

Manganese is a neurotoxin that accumulates in the brains of patients with cirrhosis and portosystemic shunts. Levels of manganese correlate with hyperintensity of nucleus pallidus seen on MR brain scans of patients with cirrhosis. These patients may also demonstrate extrapyramidal signs, suggesting that altered homeostasis of manganese and other minerals could be responsible for the cognitive deficits associated with liver cirrhosis.

3.6 Systemic inflammatory response

Inflammatory response may be an important factor that may contribute to the development of MHE and its progression to OHE. Inflammation elsewhere in the body may precipitate encephalopathy through the action of cytokines and bacterial lipopolysaccharide on astrocytes. A recent study reported that severity of MHE was independent of severity of liver disease and levels of blood ammonia but markers of inflammation (higher neutrophil counts, C-reactive protein levels, and interleukin-6 levels) were significantly higher in those with MHE compared to those without MHE. Same authors showed that induced hyperammonemia resulted in significantly greater deterioration in psychometric tests in cirrhotic patients who had an ongoing infection compared with those in whom the infection had resolved. These two studies suggest that inflammation plays a synergistic role with ammonia in producing and modulating MHE.

3.7 Intestinal flora

Intestinal flora and endotoxins are another link between inflammation, ammonia and MHE. Imbalance of intestinal flora among cirrhotics compared to normal healthy controls has been demonstrated in the study of Zhao et al. They found increase in the counts of aerobes (such as Enterobacter and Enterococcus) and anaerobes (such as Clostridium) and a decrease in

www.intechopen.com
the count of *Bifidobacterium*. The severity of imbalance in intestinal flora matched the degree of liver dysfunction. Liu et al.\textsuperscript{36} reported that cirrhotic patients with MHE had substantial derangements in the gut microecology, with significant fecal overgrowth of potentially pathogenic *Escherichia coli* and *Staphylococcus* species. Treatment with synbiotics significantly increased the fecal content of non-urease-producing *Lactobacillus* species at the expense of these other bacterial species. Such modulation of gut flora was associated with a significant reduction in blood ammonia levels and reversal of MHE in 50% of patients. Synbiotic treatment was also associated with a significant reduction in endotoxemia. The CTP functional class improved in nearly 50% of the patients.

4. Clinical characteristics

OHE is traditionally classified into four grades according to the West Haven criteria (Table 2).\textsuperscript{6}

Adapted from Mullen KD\textsuperscript{6}

Table 2. West Haven criteria for semiquantitative grading of mental state

Patients with MHE have a normal neurological examination; however they may still be symptomatic. Symptoms relate to disturbances in sleep, memory, attention, concentration and other areas of cognition.\textsuperscript{37,38} A classic sign of HE is a sleep disturbance. On a sleep questionnaire, disturbance is seen in 47% of cirrhotics compared to 4.5% of controls.\textsuperscript{37} A higher frequency of sleep disturbance in cirrhotic patients with MHE has been confirmed in studies using HRQOL questionnaires.\textsuperscript{39,40} Sleep disturbance in cirrhosis is not associated with cognitive impairment; thus it may not truly be an MHE symptom. Unsatisfactory sleep is associated with higher scores for depression and anxiety, raising the possibility that the effects of chronic disease may underlie the pathogenesis of sleep disturbance.\textsuperscript{41} Disturbances in cirrhotics may also be related to abnormalities of circadian rhythm.
Defective memory may be a sign of MHE. Patients with MHE have impaired short- and long-term memory. This impairment is predominantly related to deficits in attention and visual perception. Memory deficit of MHE seems to comprise short-term but not long-term memory impairment. This can be described as an encoding defect, in which memory recall (or retrieval) is intact.

Several cognitive statements (i.e. complaints), have predictive value for MHE, including impaired psychomotor performance ('I have difficulty doing handwork; I am not working at all'); impaired sleep or rest ('I spend much of the day lying down in order to rest'); decreased attention ('I am confused and start several actions at a time'); and poor memory ('I forget a lot; for example, things that happened recently, where I put things, etc.').

5. Health-related quality of life

5.1 Effect of MHE on daily functioning

MHE adversely affects HRQOL. Cognitive impairment in MHE mainly affects complex activities involving attention, information processing and psychomotor skills such as driving a car, planning a trip, etc. whereas basic activities of daily life, such as shopping, dressing, personal hygiene, etc. are preserved. Patients with MHE had a significant impairment of daily functioning, such as social interaction, alertness, emotional behavior, sleep, work, home management, recreation and pastimes compared with cirrhotic patients who did not have MHE. Treatment with lactulose improved both cognitive functions and HRQOL; improvement in the latter was linked to improvement in cognitive function.

5.2 Effect of MHE on driving

MHE adversely affects driving skills. Patients with MHE have higher rates of traffic violations and motor vehicle accidents. Schomerus et al. were the first to demonstrate a negative effect of psychomotor deficits in patients with MHE on driving fitness. Similar results were reported by Watanabe et al. and Wein et al. found that the fitness to drive a car was impaired in cirrhotic patients with MHE using a standardizad 90-minute on-road driving test. Increased risk of automobile accidents was related to a decline in cognitive function. Impairment in attention and speed of mental processing adversely affects an individual’s ability to react to unexpected traffic conditions. Patients with MHE have higher rates of traffic violations and motor vehicle accidents. Patients with MHE also had impaired navigation skills. Navigation, required for safe driving, is a complex process that depends on functioning working memory, attention, and speed of mental processing; impairment in navigation skills correlated with impairment in response inhibition and attention.

6. Diagnosis of MHE

The absence of clinical evidence of hepatic encephalopathy is key to the diagnosis of MHE and can only be determined by a detailed assessment of the patient history and a comprehensive neurological assessment of consciousness, cognitive, and motor function.

Various tools have been evaluated for the diagnosis of MHE and include the neuropsychological tests, computerized tests, short neuropsychological and computerized test batteries and neurophysiological tests. Regional cerebral blood flow changes, and
magnetic resonance imaging and spectroscopy, though useful for understanding pathogenic mechanisms, are currently not considered of diagnostic value.

6.1 Neuropsychological tests

Neuropsychological testing is an established methodology for quantifying cognitive impairment due to various forms of encephalopathy, including low-grade or minimal hepatic encephalopathy. Neuropsychological tests directly measure cognitive functions that are directly relevant to activities of daily living. They have been applied for the diagnosis of HE for more than 50 years. In the fifties, measures like the construction or reproduction of a five-pointed star (Fig. 1.) or a coil and handwriting have been used for the diagnosis of HE. Sometimes even more complex figures were presented to the patients to be reproduced. Although all tests were able to depict an increase or decrease of the constructional ability of a patient, it was extremely difficult to quantify the test result. In general, psychometric tests have to fulfill the following criteria: they have to be objective, reliable, valid and sensitive.

![Star construction test](image)

Fig. 1. Star construction test

The neuropsychological features of MHE point to a disorder of executive functioning, particularly selective attention, visuospatial abilities and fine motor skills. Although these domains are most commonly implicated in MHE, impairments of memory have also been reported.

The attentional impairments in MHE are observed on a variety of measures. These include measures of cognitive processing speed involving psychomotor responding, such as the Number Connection test A (NCT-A), the Number Connection test B (NCT-B), block design test (BDT), the Digit Symbol test (DST), Line drawing test, Circle dotting, Serial-dotting test (SDOT), Figure connection test. Impairments on measures of cognitive processing speed and response inhibition that do not require a motor response have also been reported (e.g. with verbal fluency tasks and measures such as the Stroop test). Visuospatial impairments have been primarily reported on block design tasks (which also include a motor/practic component), but also on more pure measures of visuospatial perception, such as line orientation or the Hooper test. Fine motor skill impairments have been noted on measures such as the grooved pegboard task and on line tracing tasks (the latter also involve visuospatial abilities).
Psychometric test batteries that shall be used for the diagnosis of MHE ought to examine exactly the fields of cognition: visual perception, visuo-spatial orientation, visual construction, concentration, attention and memory.29

The small number of neuropsychological tests represent the cerebral disfunction of MHE. This were: the Number Connection test A (NCT- A), the Number Connection test B (NCT-B), block design test (BDT), the Digit Symbol test (DST), Line drawing test, Circle dotting. Time-tested with well recognized clinical significance, established.

The number connection test (NCT) is the most widely used test in the psychometric assessment of cirrhotic patients. It was found to be capable of detecting mild mental dysfunction in cirrhotic patients.

The NCT-A (Fig.2) is a test of visuo-spatial orientation and psychomotor speed. The subject is shown a sheet of paper with 25 numbered circles which are randomly spread over the paper. The task is to connect the circles from 1-25 as quick as possible. Test result is the time needed by the subject including error correction time.68

![Fig. 2. Number Connection test A (NCT-A)](image)

![Fig. 3. Number Connection test B (NCT– B)](image)

The NCT-B (Fig.3) is quite similar. The circles include the numbers from 1-13 and the letters from A-L. The subjects are asked to connect numbers and letters in alternating manner, that means go from 1-A-2-B-3-C and so on. Test result is the time needed including error correction time. Besides visuo-spatial orientation and psychomotor speed this test is appropriate to study the ability to shift attention.68

The Block Design Test (BDT) is a test of visuo-spatial and motor skills (Fig.4). The task is to take 6-9 blocks that have all white sides, all red sides, and red and white sides and arrange them according to a pattern formed by examiner or shown on a card. Scored for speed and accuracy.69

![Fig. 4. Block Design Test (BDT)](image)
The Digit Symbol test (DST) (Fig. 5) - the subject is given a series of double-boxes with a number given in the upper part. The task is to draw a symbol pertinent to this number into the lower part of the boxes. Nine fixed pairs of numbers and symbols are given at the top of the test sheet. Test result is the number of boxes correctly filled within 90 seconds. Pathological test results indicate a deficit in visuo-constructive abilities, especially.

Fig. 4. The Block Design Test (BDT)

Fig. 5. The Digit Symbol test (DST)
The line drawing test (Fig. 6) is a test of motor speed and accuracy. The patients have to follow the route of this labyrinth without crossing or even touching the borderlines.\textsuperscript{20}

![Fig. 6. The line drawing test](image)

For the assessment of the test result, the whole route is divided into small sections (Fig. 7) and each touching or crossing the border in a section is counted. The number of mistakes and the time needed to go through the labyrinth, both, are test results.\textsuperscript{20}

![Fig. 7. Division of the whole route of the line drawing test for the assessment of the errors.](image)

The circle dotting test (Fig. 8) is the most simple test of the battery. It is a test of pure motor speed. The subjects are asked to put a dot in each of the 100 circles given on the sheet, after they have prepared by dotting the 20 circles at the top of the sheet, first. Test result is the time needed.

![www.intechopen.com](image)
The Working Party recommends that the diagnosis of MHE requires a normal mental status examination and impairment in the performance of at least two of the following tests: NCT-A, or figure connection test-A (FCT-A), NCT-B, BDP, DST.\textsuperscript{41}

In 2009, the Commission on Neuropsychological Assessment of Hepatic Encephalopathy concluded that neuropsychological test batteries aimed at measuring multiple domains of cognitive function are generally more reliable than single tests, and tend to be more strongly correlated with functional status.\textsuperscript{71} Both the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS)\textsuperscript{72} and PSE-Syndrom-Test\textsuperscript{73} may be used for this purpose.

The PSE-Syndrom-Test, developed in Germany and validated in several other European countries, incorporates older assessment tools such as NCT-A and NCT-B, the line-tracing test (LTT), the serial-dotting test (SDT), and DST.

The psychometric hepatic encephalopathy score (PHES) is a standardized test battery including NCT-A and B, the line-tracing test for time ($t$) and error ($e$), the serial-dotting test, and the digit symbol test. This battery examines many of the abnormalities seen in patients with MHE, including motor speed and accuracy, visuo-spatial orientation, visual perception, visual construction, attention, concentration, and, to a lesser extent, memory. PHES has a prognostic value for the occurrence of overt HE and mortality in cirrhotic patients.\textsuperscript{74,75}
The RBANS contains measures of verbal and visual anterograde memory, working memory, cognitive processing speed, language (including semantic fluency) and visuospatial function (line orientation and figure copy). It is a portable pencil-and-paper test that requires a folding stimulus booklet and paper record form to administer. Administration time is approximately 20–25 min. In the study of Sorrel et al. RBANS scores were strongly correlated with liver disease as measured by the model for end-stage liver disease staging. Scores on the RBANS also predicted disability independently of liver disease severity in this study.

Use of either the RBANS or the PSE-Syndrom-Test is recommended for diagnosing and monitoring minimal hepatic encephalopathy. The choice of which battery to use should be based upon the availability of local translations and normative data.

6.2 Neurophysiological tests

Quantitative neurophysiologic tools include Simple electroencephalography (EEG), evoked potentials (auditory, visual, Somatosensory) and P300 (type of auditory evoked potential). Changes in EEG/evoked responses are non-specific.

The major finding on EEG is a general decrease in wave frequency and an increase in wave amplitude. First, so-called theta-waves with a frequency between 4 and 7 cps occur, then these theta waves predominate and are committed by delta waves with a frequency of 1-3 cps. Preterminally there is a loss of wave amplitude and a flattening of the curve. These abnormalities may be found even in cirrhotics without clinical signs of encephalopathy. There is no close correlation between the grade of HE and the degree of EEG abnormalities. The sensitivity of the EEG for the diagnosis of subclinical HE is limited compared to psychometric tests. The EEG is useful for follow-up examinations, predominantly.

Among EEG variations, the most sensitive test is computer-assisted analysis, including the mean dominant EEG frequency and the power of a particular rhythm. Quantified-EEG has a prognostic value for occurrence of bouts of overt HE and mortality in cirrhotic patients. Among evoked responses, the P300 peak obtained in an auditory oddball paradigm is the most sensitive test. These tests can supplement neurological or neuropsychiatric examination. It has been demonstrated that there was a greater likelihood of development of overt HE in cirrhotic patients with abnormal P300 event-related potential latencies and NCT than in patients with no such abnormality.
Neurophysiological tests can be used during follow up to demonstrate change in a patient’s condition. Their major limitations are: (i) need for specialized equipment and technical expertise for evaluation and interpretation; and (ii) inability to perform these tests in an outpatient clinic.\(^{41}\)

The changes observed in cerebral blood flow and metabolism in SPET, PET, and \(^1\)H and \(^31\)P MRS studies reflect the pathogenic process that underlies the condition rather than providing diagnostic information. Similarly, the morphological brain abnormalities identified in this population, including mild brain oedema, hyperintensity of the globus pallidus and other subcortical nuclei observed in cerebral MR studies, and the central and cortical atrophy observed in neural imaging studies, are unlikely to have diagnostic utility.\(^{4}\)

### 6.3 Computerized tests

Computerized psychometric tests measuring both the reaction time and the accuracy of performing tasks requiring psychomotor speed, attention, short-term memory, or choice ability.

Critical flicker frequency (CFF) tests the ability of a patient to perceive flickering and its fusion threshold. The CFF threshold measures visual discrimination and general arousal.\(^{84}\)

CFF is a simple, reliable and accurate method for the diagnosis of MHE. The technique shows little dependence on age, education or training.\(^{75,85}\)

Inhibitory control test (ICT) is a computerized test of attention and response inhibition that has been used to characterize attention deficit disorder, schizophrenia and traumatic brain injury. ICT has been validated for the diagnosis of MHE in USA and found to be reliable and sensitive for detection as well as follow-up of patients with MHE.\(^{86}\)

### 6.4 Magnetic resonance imaging and spectroscopy

Magnetic resonance imaging (MRI) identified the morphological brain abnormalities in the population of patients with cirrhosis, including mild brain oedema, hyperintensity of the globus pallidus and other subcortical nuclei, and central and cortical atrophy. High-signal abnormalities on T1-weighted images in the globus pallidum have been observed in cirrhotic patients, even without clinical evidence of HE. Deposition of manganese is regarded as the most likely explanation of this high-signal abnormality.\(^{87}\) There is no direct correlation between pallidal hyperintensity and grade of encephalopathy.\(^{88}\) Basal ganglia T1-weighted signal intensity and manganese accumulation appear to be related to the underlying degree of portal-systemic shunting rather than directly to neuropsychiatric impairment.\(^{89}\) Hyperintense globus pallidus on MRI is common in patients with liver cirrhosis and also occurs in patients with noncirrhotic portal hypertension.

Magnetic resonance spectroscopy (MRS) shows a decrease in myo-inositol/creatinine and choline/creatinine ratios in the white matter with an increase in the Glx (glutamine and glutamate) concentration in the basal ganglia in patients with MHE.\(^{91,92}\) Liver transplantation as well as lactulose therapy have been shown to reverse these changes at 4 weeks and later after transplantation.\(^{91}\) However, the ability of MRS to differentiate between cirrhotic patients without HE and those with MHE has not been conclusively shown.\(^{41}\)

Diffusion-weighted imaging allows assessment of intracellular and extracellular water content in the brain, which helps in differentiating cytotoxic from vasogenic edema.\(^{93}\)
Diffusion tensor imaging has revealed that mean diffusivity, a measure of water movement across cell membranes, is significantly higher in patients with MHE in the regions of the corpus callosum, internal capsules, caudate nuclei and occipital white matter. Increase in mean diffusivity indicates the presence of interstitial brain edema. Mean diffusivity values increase as the grade of HE increases, suggesting that brain edema present in patients with HE may contribute to its pathogenesis. Mean diffusivity values decreased significantly and there was a corresponding improvement in neuropsychological test scores in patients with MHE after three weeks of lactulose therapy. MR imaging techniques therefore complement neuropsychological evaluation of MHE.

7. Diagnostic criteria for MHE

The diagnostic criteria for MHE have not been standardized but rest on careful patient history and physical examination, normal mental status examination, demonstration of abnormalities in cognition and/or neurophysiological function, and exclusion of concomitant neurological disorders.

No consensus on diagnostic criteria or diagnostic tests has been established.

- Cirrhotic patients
  - Without clinical signs of encephalopathy
  - Perform worse in psychometric tests when compared with healthy controls
  - Affects an estimated 60% (50% to 80%) of patients with cirrhosis
- Cerebral dysfunction has a major impact on patients’ daily living
  - The presence of a disease that can cause MHE, such as, cirrhosis and/or the presence of a portal systemic shunt
  - normal mental status on clinical examination
  - demonstration of abnormalities of cognition and/or neurophysiological variables
  - exclusion of concomitant neurological disorders.

The INASL Working Party recommends that all patients with cirrhosis be screened for the presence of MHE using a standard battery of psychometric tests, PHES, CFF or ICT, depending upon the availability of tests and their validation for local populations from different parts of the world (Fig. 1). Patients whose index psychometric or computerized test results do not indicate pathology should be screened every 6–12 months.

It has been shown conclusively that cognitive functions improve with therapy for MHE. Such therapy may improve HR QOL of patients with MHE and delay the development of HE. Hence all patients with liver cirrhosis should be subjected to testing for MHE. Special attention should be given to those who have cognitive symptoms and high-risk groups such as active drivers, patients handling heavy machines or reporting decline in work performance.

8. Natural history

8.1 Development of overt hepatic encephalopathy

Patients with MHE may improve, remain unchanged or deteriorate and develop overt HE over a long-term follow-up.
The frequency of MHE increases as the severity of liver disease increases. In view of a high frequency of MHE in patients with liver disease, it is important to understand its impact on future clinical outcomes, such as occurrence of overt HE, quality of life and survival, and to determine whether treatment of MHE can induce improvements in these outcomes.

Several studies that looked at the frequency of development of overt HE in cirrhotic patients found that those with MHE developed overt HE more often during follow up than those without MHE. In addition, some studies have shown an increased risk of death in patients with liver cirrhosis and MHE compared to those without MHE. However, patients with MHE had poorer liver function than those without MHE in these studies, making it difficult to ascribe the poor outcome to the presence of MHE. Das et al. studied the relationship of progression of MHE to overt HE in relation to the severity of liver dysfunction and found that the rate of progression to overt HE was much higher in patients with MHE and a CTP score > 6 than in those with MHE and a CTP score = 6. Amodio et al. found that the presence of MHE and that of liver dysfunction were both associated with mortality on univariate analysis; however, on multivariate analysis, liver functional status was the only independent predictor of mortality. In another study, progression of MHE to overt HE was associated with abnormal response to oral glutamine challenge, which in turn was associated with poor liver function. Furthermore, MHE in patients with preserved liver function but large portal-systemic shunts (congenital shunts, non-cirrhotic portal hypertension and cirrhosis with preserved liver function) appears to have a good outcome, even though these data are based on a small number of patients. Thus, it appears that the higher risk of overt HE or death in patients with MHE may not be related to MHE per se but to the poorer liver function in patients with MHE.

9. Survival

Current data suggest that patients with MHE tend to have more frequent episodes of overt HE and poorer survival than in those without MHE, and indicate that patients with MHE have a more advanced liver disease. Child-Turcotte-Pugh score and PHES were associated with a poor prognosis.

10. Treatment

Ammonia plays a key role in the pathogenesis of MHE. Empiric therapy is based on the principle of reducing the production and absorption of ammonia in the gut—a number of agents are beneficial for this purpose.

10.1 Nutritional interventions

The European Society for Parenteral and Enteral Nutrition recommended, in 2006, that patients with cirrhosis must eat at least 1.2 g/kg of protein daily. They also recommended that the diet of patients with cirrhosis should be supplemented with branched-chain amino acids (BCAAs) and vegetable protein once HE has developed. Vegetable-based protein is better tolerated by patients with cirrhosis than meat-based protein.
10.2 Pharmacological therapy

Non-absorbable disaccharides include lactulose and lactitol. Treatment for MHE may be initiated with lactulose; patients should receive 30–60 mL of lactulose in two or three divided doses so that they pass two to three semi-soft stools per day. Although the appropriate duration of therapy for MHE is unsettled, at least three studies suggest that treatment may be advised for 3–6 months.\(^{3,67,95}\)

Lactulose decreases blood ammonia levels, and improves psychometric performance and HRQOL.\(^{3,59,62,64,67,91–95}\) Using cerebral diffusion tensor imaging, Kale et al.\(^{59}\) showed that interstitial brain edema observed in patients with MHE resolves after treatment for 3 weeks with lactulose in parallel with improvements in neuropsychiatric performance.

Prasad et al.\(^{3}\) studied the effect of treatment of MHE with lactulose on psychometric performance (measured by NCT, FCT-A, FCT-B, picture completion and block-design tests) and HRQOL (measured by Sickness Impact Profile [SIP]). Patients with MHE showed significant impairment in 11 scales of the SIP, the psychosocial and physical subscores, and in the total SIP. Patients received 30–60 mL of lactulose in two or three divided doses so that the patient passed two to three semi-soft stools per day. Following lactulose therapy for 3 months, both psychometric performance and HRQOL improved; MHE reversed in 64.5% of treated patients compared with 6.7% in the no-treatment group\((P < 0.0001)\). Significant improvement was found in five (emotional behavior, ambulation, mobility, sleep/rest and recreation and pastimes) of the 12 scales of the SIP and in the total psychosocial and physical sub-scores in the treated patients compared with the untreated patients. Improvement in HRQOL was linked to improvement in cognitive function. A recent study that compared lactulose, a probiotic and LOLA with no treatment, confirmed these findings.\(^{67}\)

Branch-chain amino acids, flumazenil, L-ornithine L-aspartate, acetyl L-carnitine, and probiotics/synbiotics. A majority of these attempts were aimed at reducing blood ammonia level, and most studies have shown improvement in psychometric measurements, ammonia levels, cerebral edema and health-related quality of life (HRQoL).

10.3 Prebiotics, probiotics or synbiotics

Prebiotics, probiotics or synbiotics (probiotics and fermentable fiber) are effective in treating patients with MHE\(^{63–67}\) and can also be used as long-term therapy. Liu et al.\(^{65}\) showed that modulation of gut microecology and acidification of gut lumen in patients with liver cirrhosis and MHE by treatment with synbiotics resulted in increased fecal content of non-urease-producing \textit{Lactobacillus} species, whereas the number of urease-producing pathogenic \textit{Escherichia coli} and \textit{Staphylococcus} species decreased. This effect persisted for 14 days after cessation of supplementation. It was associated with a significant reduction in blood ammonia and endotoxin levels and reversal of MHE in nearly 50% of the patients. The severity of liver disease, as assessed according to CTP class, also improved in nearly 50% of
the patients. In a recent randomized control trial, supplementation with probiotic yogurt resulted in a significant reversal of MHE in the group receiving yogurt compared to no treatment. Treatment with a probiotic preparation also improves HROQL.

Prebiotics, probiotics or synbiotics are efficacious in the treatment of HE by decreasing bacterial urease activity, pH in the gut lumen, ammonia absorption and total ammonia in the portal blood, and by improving nutritional status of gut epithelium resulting in decreasing intestinal permeability. In addition, they help ameliorate the inflammation and oxidative stress in the hepatocytes, leading to increased hepatic clearance of ammonia. These mechanisms may be additive or synergistic in treating MHE. Probiotics may represent a safe, effective, long-term therapy for MHE and may be an alternative to lactulose.

10.4 L-ornithine–L-aspartate

Clinical studies evaluating the role of LOLA in the treatment of MHE did not show its effectiveness; however, these studies were small and underpowered. A recent study that compared lactulose, a probiotic and LOLA with no treatment, however, showed that LOLA is as effective as lactulose or a probiotic preparation in improving psychometric performance and HROQL. Larger prospective studies are warranted to evaluate the role of LOLA before it can be recommended for the treatment of MHE.

10.5 Antibiotics

The role of antibiotics in MHE has not been evaluated. Prospective studies with poorly absorbed antibiotics are required to evaluate their efficacy in improving MHE.

Antibiotics: Rifaximin, Neomycin
