Chapter 15

Wind Diesel Hybrid Power System with Hydrogen Storage

Mamadou Lamine Doumbia, Karim Belmokhtar and Kodjo Agbossou

Additional information is available at the end of the chapter

http://dx.doi.org/10.5772/52341

1. Introduction

By 2050 the demand for energy could double or even triple as the global population grows and developing countries expand their economies. Energy prices, supply uncertainties, and environmental concerns are driving many countries to rethink their energy mix. The International Energy Agency’s Energy Technology Perspectives 2008 publication projects that energy sector emissions of greenhouse gases (GHGs) will increase by 130% over 2005 levels, by 2050, in the absence of new policies (IEA, 2008).

Renewable energy is part of the solution for the energy problem, and wind energy is one of the cost-effective options for the generation of electricity. The main applications are the generation of electricity and water pumping.

By the end of 2007, in the world, there were around 100,000 wind turbines installed in wind farms, with an installed capacity of 94,000 megawatts, which generated around 300 TWh/year. Wind energy is now part of national policies for generation of electricity in many countries (Vaughn Nelson, 2009).

In 2007, in Europe there were 57,000 MW installed wind power, which generated 3.7% of the electrical demand. The European goal is 20% of electricity generated by renewables by 2020, of which 12–14% would be from wind. In 2010, wind energy provided for nearly 26% of electricity consumption in Denmark, more than 15% in Portugal and Spain, 14% in Ireland and nearly 9% in Germany, over 4% of all European Union (EU) electricity, and nearly 2.9% in the United States (US Department of Energy, 2011). In the future, many countries around the world are likely to experience similar penetration levels as wind power is increasingly considered not only a means to reduce CO₂ emissions but also an interesting economic alter-
native in areas with appropriate wind speeds. Since 2000, cumulative installed capacity has grown at an average rate of around 30% per year. In 2008, more than 27 GW of capacity were installed in more than 50 countries, bringing global capacity onshore and offshore to 121 GW. Wind energy in 2008 was estimated by the Global Wind Energy Council to have generated some 260 million megawatt hours of electricity. Applications for generation of electricity are divided into the following categories: utility-scale wind farms and small wind turbines (less than 100 kW).

Currently, for remote communities and rural industry the standard is diesel generators. Remote electric power is estimated at over 11 GW, with 150,000 diesel gensets, ranging in size from 5 to 1,000 kW. In Canada, there are more than 800 diesel gensets, with a combined installed rating of over 500 MW in more than 300 remote communities (Vaughn Nelson, 2009). Diesel generators are inexpensive to install; however, they are expensive to operate and maintain, and major maintenance is needed from every 2,000 to 20,000 hours, depending on the size of the diesel genset.

Wind–diesel is considered because of the high costs for generating power in isolated systems. In near future, the market of wind–diesel systems will grow up because of the high cost of diesel fuel. Wind–diesel power systems can vary from simple designs in which wind turbines are connected directly to the diesel grid, with a minimum of additional features, to more complex systems.

There are a number of problems in integrating a wind turbine to an existing diesel genset: voltage and frequency control, frequent stop–starts of the diesel, utilization of surplus energy, and the use and operation of a new technology. These problems vary by the amount of penetration. Wind turbines at low penetration can be added to existing diesel power without many problems, as it is primarily a fuel saver. However, for high wind penetration, storage is needed. Moreover, one of the major drawbacks of wind energy is its unpredictability and intermittency. So, to supply better consumers' energy needs, wind systems have to operate with storage devices. Several energy storage methods have been in development over the past several years. This includes compressed air, pumped hydro, flow battery flywheel, hydrogen storage, etc. It has been proved (E.I. Zoulias, N. Lymberopoulos, 2008; Nelson et al., 2006) that hydrogen can be effectively used as storage medium for intermittent renewable energy sources (RES)-based autonomous power systems. More specifically, excess of RES energy produced from such systems at periods of low demand can be stored in the form of hydrogen, which will be used upon demand during periods when the wind energy is not available.

For many years, Hydrogen Research Institute (HRI) has developed a renewable photovoltaic/wind energy system based on hydrogen storage (M. L. Doumbia et al., 2009; K. Agbossou et al., 2004). The system consists of a 10 kW wind turbine generator (WTG) and a 1 kW solar photovoltaic (PV) array as primary energy sources, a battery bank, an 5 kW electrolyzer, a 5 kW fuel cell stack, different power electronics interfaces for control and voltage adaptation purposes, a measurement and monitoring system. This renewable energy system is scaled for residential applications size and can be operated in stand-alone or grid-connected mode and different control strategies can be developed.
Numerical modelling is an important part of the design, assessment, implementation and evaluation of autonomous power systems with wind power.

This chapter is devoted to a large scale wind-diesel Hybrid Power System (HPS) applications. It presents theoretical analysis, modelling and control of Wind Energy Conversion Systems (WECS) connected to an autonomous power system with hydrogen storage. The wind generator under study is a Doubly Fed Induction Generator (DFIG) type. The models of the main components (mainly wind turbine, generator, diesel genset, electrolyzer) will be derived. The wind turbine’s maximum power point tracking technique will be presented and a power transfer strategy in the interconnected system will be analysed. Performance of the control method is validated to maintain the hybrid power system’s frequency. The effectiveness of the proposed hybrid system is validated by simulation using Matlab/ Simulink/ SimPowerSystems environment. The Hybrid Power System (HPS) is composed of a 600 kW diesel genset, three 190 kW wind turbines, three 80 kW alkaline electrolyzers and a 610 kW maximum load.

2. Wind-diesel power system with hydrogen storage

The structures of Hybrid Power System (HPS) can be classified into two categories: AC coupled and DC-coupled (T. Zhou, 2009).

In an AC-coupled HPS, all sources are connected to a main AC-bus before being connected to the grid. In AC-coupled structure, different sources can be located anywhere in the microgrid with a long distance from each other. However, the voltage and the frequency of the main AC bus should be well controlled in order to ensure the stability of the system and the compatibility with the utility network.

In a DC-coupled HPS, all sources are connected to a main DC-bus before being connected to the grid through a main inverter. In a DC-coupled structure, the voltage and the frequency of the grid are independent from those of each source.

However, not all HPSs can be classified into AC or DC-coupled system, since it is possible to have both coupling methods, then a Mixed HPS is obtained. In this case, some advantages can be taken from both structures.

The wind-diesel HPS configuration studied in this work is represented in Fig. 1.

2.1. Wind turbine

Wind turbines come in different sizes and types, depending on power generating capacity and the rotor design deployed. Small wind turbines with output capacities below 10 kW are used primarily for residences, telecommunications dishes, and irrigation water pumping applications. Utility-scale wind turbines have high power ratings ranging from 100 kW to 5 MW. Current wind farms with large capacity wind turbine installations are
capable of generating electricity in excess of 500M MW for utility companies (Vaughn Nelson, 2009).

Modern wind turbines are classified into two configurations: horizontal-axis wind turbines (HAWTs) and vertical-axis wind turbines (VAWTs), depending on rotor operating principles. The VAWT configuration employs the Darrieus model named for the famous French inventor.

According to Albert Betz, the mechanical power $P_m$ captured by the turbine from the wind for a given wind speed $v_w$ is computed by the following expression (I. Munteanu et al., 2008; N.M. Miller et al., 2008).

$$P_m = \frac{1}{2} \rho AC_p(\lambda, \beta)v_w^3$$  \hspace{1cm} (1)

$\rho$ is the air density in $kg/m^3$; $A=\pi R^2$ is the area in $m^2$ swept by the blade; $R$ is the radius of the blade in $m$.

The aerodynamic model of a wind turbine can be determined by the $C_p(\lambda, \beta)$ curves. $C_p$ is the power coefficient, which is function of both tip speed ratio $\lambda$ and the blade pitch angle $\beta$. The tip speed ratio is given by:

Figure 1. Wind-diesel Hybrid Power System with hydrogen production

HAWTs with two or three blades are the most common. Wind blowing over the propeller blades causes the blades to “lift” and rotate at low speeds. Wind turbines using three blades are operated “upwind” with rotor blades facing into the wind. The tapering of rotor blades is selected to maximize the kinetic energy from the wind. Optimum wind turbine performance is strictly dependent on blade taper angle and the installation height of the turbine on the tower (Vaughn Nelson, 2009).
\[ \lambda = \frac{\Omega R}{v_w} \]  

\( \Omega \), represents the rotational speed of the wind turbine in \text{rad/sec}.

The maximum power coefficient \( C_p \) is determined by Betz as follows (S. Heier, 1998):

\[ C_p^{\text{max}}(\lambda, \beta) = \frac{16}{27} \approx 0.593 \]  

(3)

Hence, even if power extraction without any losses were possible, only 59\% of the wind power could be utilized by a wind turbine.

The power coefficient versus the ratio speed as shown in Fig. 2.

![Figure 2. Coefficient of power versus ratio of speed](http://dx.doi.org/10.5772/52341)

In our study, the mathematical representation of the power coefficient used for a wind turbine is given by:

\[ C_p = 0.398 \sin \left( \frac{\pi(\lambda - 3)}{15 - 0.3\beta} \right) - 0.00394(\lambda - 2)\beta \]  

(4)

In the aim to extract the maximum active power, the speed of the wind turbine must be adjusted to achieve the optimal value of the tip speed ratio. The block diagram of Fig. 3 shows the Maximum Power Point Tracking (MPPT) technique applied to the generator to produce maximum
power. If the wind speed is below the rated value, the WTG operates in the variable speed mode, and $C_p$ is kept at its maximum value. In this operating mode, the pitch control is deactivated. When the wind speed is above the rated value, the pitch control is activated, in the aim to reduce the generated mechanical power (W. Qiao, W. Zhou et al., 2008).

![Block diagram of the control of the velocity of the DFIG with MPPT](image)

**Figure 3.** Block diagram of the control of the velocity of the DFIG with MPPT

2.2. Doubly-fed induction generator and its control

**a. Doubly-Fed induction Generator**

Today, the wind turbines on the market mix and match a variety of innovative concepts with proven technologies both for generators and for power electronics. Wind turbines can operate either with a fixed speed or a variable speed. Most commonly used types of wind turbines generators are asynchronous (induction) and synchronous generators. Among these technologies, asynchronous Doubly Fed Induction Generator (DFIG) has received much attention as one of preferred technology for wind power generation (Fig.4). The DFIG consists of a Wound Rotor Induction Generator (WRIG) with the stator windings directly connected to the constant-frequency three-phase grid and with the rotor windings mounted to a bidirectional back-to-back IGBT voltage source converter. The converter compensates the difference between the mechanical and electrical frequency by injecting a rotor current with a variable frequency. The power converter consists of two converters, the rotor-side converter and grid-side converter, which are controlled independently of each other. The main idea is that the rotor-side converter controls the active and reactive power by controlling the rotor current components, while the line-side converter controls the DC-link voltage and ensures a converter operation at unity power factor (i.e. zero reactive power). Compared to a full rated converter system, the use of DFIG in a wind turbine offers many advantages, such as reduction of inverter cost, the potential to control torque and a slight increase in efficiency of wind energy extraction. Depending on the operating
condition of the drive, power is fed into or out of the rotor: in an oversynchronous mode, it flows from the rotor via the converter to the grid, whereas it flows in the opposite direction in a subsynchronous mode. In both cases – subsynchronous and oversynchronous – the stator feeds energy into the grid (T. Ackermann, 2005).

Figure 4. Structure of the DFIG based wind system

The stator and rotor voltages of the DFIG are given by the following expression (Y. Ren, H. Li and J. Zhou, 2009; R. G. De Almeida et al., 2004).

\[
\begin{align*}
    v_{ds} &= r_s i_{dh} + \frac{d\lambda_{ds}}{dt} - \omega_s \lambda_{qs} \\
    v_{qs} &= r_s i_{qs} + \frac{d\lambda_{qs}}{dt} + \omega_s \lambda_{ds} \\
    v_{dr} &= r_r i_{dr} + \frac{d\lambda_{dr}}{dt} - \omega_r \lambda_{qr} \\
    v_{qr} &= r_r i_{qr} + \frac{d\lambda_{qr}}{dt} + \omega_r \lambda_{dr}
\end{align*}
\]

(5)

\[r_s\text{ and } r_r\text{ are respectively the resistance of the stator and rotor windings, and } \omega_{s}\text{ is the rotational speed of the synchronous reference frame.}\]

\[
\begin{align*}
    \lambda_{ds} &= L_s i_{ds} + L_m i_{dr} \\
    \lambda_{qs} &= L_s i_{qs} + L_m i_{qr} \\
    \lambda_{dr} &= L_r i_{dr} + L_m i_{dh} \\
    \lambda_{qr} &= L_r i_{qr} + L_m i_{qs}
\end{align*}
\]

(6)

\[L_s\text{ and } L_r\text{ represent respectively the self-inductance of the stator and the rotor windings, and } L_m\text{ is the mutual inductance between the stator and the rotor windings.}\]

The electromagnetic torque of the DFIG can be expressed as follow:
\[ T_{em} = P(\lambda_{ds} i_{qs} - \lambda_{qs} i_{ds}) \]  \hspace{1cm} (7)

\( P \) is the number of pole pairs.

To achieve independent control of the stator active power and stator reactive power, a vector-control approach is used. \( d-q \) axis connected to the stator’s rotating field is chosen and quadratic component of the stator flux is set to zero. The power control is performed through the back to back converter connected to the rotor. Then, the stator voltages can be given according the rotor currents as (D. Aouzellag et al. 2006).

The stator’s flux and current equations are:

\[
\begin{align*}
\lambda_{ds} &= L_s i_{ds} + L_m i_{d} \\
\lambda_{qs} &= L_s i_{qs} + L_m i_{q} \\
i_{ds} &= \frac{\Phi_s}{L_s} - \frac{L_m}{L_s} i_{d} \\
i_{qs} &= -\frac{L_m}{L_s} i_{q} \\
\end{align*}
\]  \hspace{1cm} (8)

\[
\begin{align*}
i_{ds} &= \frac{\Phi_s}{L_s} - \frac{L_m}{L_s} i_{d} \\
i_{qs} &= -\frac{L_m}{L_s} i_{q} \\
\end{align*}
\]  \hspace{1cm} (9)

Fom equations (5) et (6), rotor’s voltages can be rewritten as:

\[
\begin{align*}
v_{dr} &= r i_{ds} + \frac{d}{dt} \left(L_s i_{ds} + L_m i_{d} \right) - \omega_s \left(L_s i_{qs} + L_m i_{q} \right) \\
v_{qr} &= r i_{qs} + \frac{d}{dt} \left(L_s i_{qs} + L_m i_{q} \right) + \omega_s \left(L_s i_{d} + L_m i_{d} \right) \\
v_{dr} &= r i_{ds} + \frac{d}{dt} \left(L_s i_{ds} + L_m i_{d} \right) - \omega_s \left(L_s i_{qs} + L_m i_{q} \right) + \omega_s \left(L_s i_{d} + L_m i_{d} \right) \\
v_{qr} &= r i_{qs} + \frac{d}{dt} \left(L_s i_{qs} + L_m i_{q} \right) + \omega_s \left(L_s i_{d} + L_m i_{d} \right) + \omega_s \left(L_s i_{d} + L_m i_{d} \right) \\
v_{dr} &= r i_{ds} + \frac{d}{dt} \left(L_s i_{ds} + L_m i_{d} \right) - \omega_s \left(L_s i_{qs} + L_m i_{q} \right) + \omega_s \left(L_s i_{d} + L_m i_{d} \right) \\
v_{qr} &= r i_{qs} + \frac{d}{dt} \left(L_s i_{qs} + L_m i_{q} \right) + \omega_s \left(L_s i_{d} + L_m i_{d} \right) + \omega_s \left(L_s i_{d} + L_m i_{d} \right) \\
\end{align*}
\]  \hspace{1cm} (10)

\[
\begin{align*}
v_{dr} &= r i_{ds} + \frac{d}{dt} \left(L_s i_{ds} + L_m i_{d} \right) - \omega_s \left(L_s i_{qs} + L_m i_{q} \right) + \omega_s \left(L_s i_{d} + L_m i_{d} \right) \\
v_{qr} &= r i_{qs} + \frac{d}{dt} \left(L_s i_{qs} + L_m i_{q} \right) + \omega_s \left(L_s i_{d} + L_m i_{d} \right) + \omega_s \left(L_s i_{d} + L_m i_{d} \right) \\
\end{align*}
\]  \hspace{1cm} (11)

\[
\begin{align*}
v_{dr} &= r i_{ds} + \frac{d}{dt} \left(L_s i_{ds} + L_m i_{d} \right) - \omega_s \left(L_s i_{qs} + L_m i_{q} \right) + \omega_s \left(L_s i_{d} + L_m i_{d} \right) \\
v_{qr} &= r i_{qs} + \frac{d}{dt} \left(L_s i_{qs} + L_m i_{q} \right) + \omega_s \left(L_s i_{d} + L_m i_{d} \right) + \omega_s \left(L_s i_{d} + L_m i_{d} \right) \\
\end{align*}
\]  \hspace{1cm} (12)
\[ v_{dr} = r_i + \left( L_r - \frac{L_m}{L_s} \right) \frac{d}{dt} - \omega_s L_m \frac{d}{dt} - \frac{L_m}{L_s} i_{dr} \]

\[ v_{dq} = r_i + \left( L_r - \frac{L_m}{L_s} \right) \frac{d}{dt} + \omega_s L_m \frac{d}{dt} + \frac{L_m}{L_s} i_{dq} \]  

(13)

\[ v_{dr} = r_i + \left( L_r - \frac{L_m}{L_s} \right) \frac{d}{dt} - \omega_s L_m \frac{d}{dt} - \frac{L_m}{L_s} i_{dr} \]

\[ v_{dq} = r_i + \left( L_r - \frac{L_m}{L_s} \right) \frac{d}{dt} + \omega_s L_m \frac{d}{dt} + \frac{L_m}{L_s} i_{dq} + \omega L_m \frac{\Phi_s}{L_s} \]  

(14)

\[ \omega_r \text{ and } \omega_s \text{ are respectively rotor and stator parameters frequencies; } s \text{ is the machine's slip.} \]

\[ \omega_s = s \omega_s \]

(15)

From vector control conditions, the stator voltage can be expressed as:

\[ V_s = \omega_s \Phi_s \]  

(16)

Then, the final vector control equations of the rotor's voltage are:

\[ v_{dr} = r_i + \left( L_r - \frac{L_m}{L_s} \right) \frac{d}{dt} - \omega_s L_m \frac{d}{dt} - \frac{L_m}{L_s} i_{dr} \]

\[ v_{dq} = r_i + \left( L_r - \frac{L_m}{L_s} \right) \frac{d}{dt} + \omega_s L_m \frac{d}{dt} + \frac{L_m}{L_s} i_{dq} \]

(17)

2. DFIG’s Control
The Rotor Side Converter (RSC) is used to control both active and reactive powers provided by the stator of the DFIG. The control strategy of the RSC is based on the power vector control of the DFIG, and the principle of this control is illustrated by Fig. 5. Different controllers can be used for this purpose.

![Figure 5. Scheme of the power control vector of the DFIG](image)

The Grid Side Converter (GSC) is used to regulate the DC-link voltage and to adjust the power factor. The GSC is a bidirectional converter which operates as a rectifier when the slip \( g \) is positive (subsynchronous mode) and as an inverter when the slip is negative (oversynchronous mode).

The active and reactive powers on the grid side are written respectively as follows (X. Yao et al. 2008):

\[
\begin{align*}
P &= \frac{3}{2} V_m i_d \\
Q &= -\frac{3}{2} V_m i_q
\end{align*}
\]  

\( V_m \) is the magnitude of voltage of the grid. The principle of control of GSC is illustrated by Fig. 6.
2.3. Diesel generator modelling

The diesel generator is composed of the diesel engine and Wound Rotor Synchronous Generator (WRSG).

a. Diesel Engine

The model of the diesel engine is shown in Fig. 7 (R. Dettmer, 1990; R. Pena et al., 2002; S. Roy et al., 1993). The dynamic of the actuator is modeled by a first order model with time constant $\tau_1$ and gain $K_1$ (R. Pena et al., 2008; S. Roy et al., 1993). The combustion block is represented with gain $K_2$ and delay $\tau_2$ (R. Dettmer, 1990).
The actuator is modelled as:

$$\frac{K_1}{1 + sr_1} \tag{19}$$

The model of the combustion bloc is given by:

$$K_2 e^{-r_2 s} \tag{20}$$

The delay can be expressed as (R. Pena et al., 2002; R. Pena et al., 2008):

$$\tau_2 = \frac{60h}{2Nn_c} + \frac{60}{4N} \tag{21}$$

$h$ represents the strokes number, $n_c$ the number of cylinders and $N$ the speed of diesel generator (rpm), $\Phi$ is the fuel consumption rate (kg/sec) (F. Jurado and J. R. Saenz, 2002). In the order to maintain constant the frequency of the grid (AC-bus), the speed of the diesel engine must be kept constant when the load varies.

2. Synchronous Generator

The simplified model of the Wound Rotor Synchronous Generator (WRSG) can be obtained in $dq$ frame (conversion between $abc$ and $dq$ can be realized by means of the Park Transform) (T. Burton et al., 2001).

The stator armature windings voltages are:

$$\begin{align*}
v_d &= -R_s j_d + \frac{d\lambda_d}{dt} - \omega \lambda_q \\
v_q &= -R_s j_q + \frac{d\lambda_q}{dt} + \omega \lambda_d
\end{align*} \tag{22}$$

$R_s$ is the stator winding resistance

The stator fluxes are

$$\begin{align*}
\lambda_d &= -L_{sd} j_d + L_{md} (j_f + j_D) \\
\lambda_q &= -L_{sq} j_q + L_{mq} i_Q
\end{align*} \tag{23}$$
Rotor armature winding voltage is

\[ v_f = -R_f i_f - L_d \frac{di_d}{dt} + L_r \frac{di_f}{dt} + L_m \frac{di_q}{dt} \]  

(24)

Damper windings are characterized by

\[
\begin{align*}
0 &= R_p i_D - L_m \frac{di_d}{dt} + L_m \frac{di_f}{dt} + L_D \frac{di_D}{dt} \\
0 &= R_Q i_Q - L_m \frac{di_q}{dt} + L_Q \frac{di_Q}{dt}
\end{align*}
\]  

(25)

To eliminate \( v_d \) and \( v_q \) in the expression of the stator voltages, we introduced the \( R_L \) load which is supplied by the synchronous generator.

\[
\begin{align*}
v_d &= R_c i_d + L_c \frac{di_d}{dt} - \omega L_c i_q \\
v_q &= R_c i_q + L_c \frac{di_q}{dt} + \omega L_c i_d
\end{align*}
\]  

(26)

By using the equations above, the state space model of the Wound Rotor Synchronous Generator (WRSG) can be written as follow (Belmokhtar et al., 2012a, Belmokhtar et al., 2012b):

\[
[\dot{X}] = [A][X] + [B][U]
\]  

(27)

Where

- \([A]\): State matrix;
- \([X]\): State vector;
- \([B]\): Control matrix;
- \([U]\): Control vector.

\([X] = [i_d, i_q, i_{fd}, i_{fq}]^T\) and \([B] = [0 0 0 v_f 0 0]^T\)

\[
\begin{align*}
\frac{di_d}{dt} &= \frac{1}{L_c + \left(\alpha - \frac{\alpha \beta}{\chi}\right)} \left(-\left(R_d + R_c\right)i_d + \alpha L_d i_q + \frac{\beta V_f}{\chi} + \frac{\beta}{\chi} R_f i_f + \left(\frac{\beta}{\chi} - 1\right) L_m i_d D - \omega L_m i_Q\right) \\
\frac{di_q}{dt} &= \frac{1}{L_c + \gamma} \left(-\alpha L_d i_d - \left(R_d + R_c\right)i_q + \omega L_m i_d f + \omega L_m i_Q\right)
\end{align*}
\]  

(28)
In order to improve the efficiency and avoid wet stacking, a minimum load of about 30% to 40% is usually recommended by the manufacturers (J. B. Andriulli et al., 1999). To achieve this goal, the values of $R_c$ and $L_{c}$ are chosen in the aim to give 35% of the rated power of the diesel generator when it is switched on. Then the partial values of the stator currents $i_{d0}$ and $i_{q0}$ in the $dq$ frame are calculated. The additional values of the stator currents $i_{d1}$ and $i_{q1}$ are computed respectively as follow:

\[
\frac{di_{d1}}{dt} = \frac{\alpha (R_c + R_s)}{\chi \delta} i_{d1} + \frac{\omega \alpha (L_q + L_s)}{\chi \delta} i_{q1} + \left( \frac{R_f}{\chi^2 \delta} \right) i_{f1} + \left( \frac{1 + \alpha \beta}{\chi^2 \delta} \right) V_f + \left( \frac{\beta - 1}{\chi} \right) \frac{L_{ml} L_{D}}{L_D} R_{f1} i_{D1} = \frac{\alpha L_{eq} L_{c}}{\chi \delta} i_{f1} \]

\[
\frac{di_{q1}}{dt} = -\frac{L_{eq} (L_q + L_s)}{L_Q (L_c + \gamma)} i_{q1} + \frac{L_{eq} (R_s + R_s)}{L_Q (L_c + \gamma)} i_{q1} + \omega \frac{L_{eq} L_{ml} L_{D}}{L_D} i_{f1} + \omega \frac{L_{eq} L_{ml} L_{ml}}{L_D} i_{m1} Q_{m1} \]

\[
T_{em} = p \left( \left( L_{d} - L_{q} \right) i_{d0} i_{q0} + L_{eq} L_{ml} \left( i_{q0} \right)^2 - L_{eq} L_{ml} i_{D1} \right)
\]

$P$ is the number of the poles.

The active additional power and the reactive power of the diesel generator are expressed respectively as:

\[
\begin{align*}
\Delta P_{add} &= v_d P_{add} + v_q Q_{add} \\
\Delta Q_{add} &= \frac{3}{2} v_d^2 + \frac{3}{2} v_q^2
\end{align*}
\]
The total stator currents of the diesel generator are:

\[
\begin{align*}
    i_{d1} &= i_{d0} + i_{d1} \\
    i_{q1} &= i_{q0} + i_{q1}
\end{align*}
\] (32)

Then, (27) is expressed as follow:

\[
T_{em} = p\left(\left(L_d - L_q\right)i_{d1}i_{q1} + L_{md1}i_{d1}i_{q1} + L_{md1q}i_{d1}i_{q1} - L_{mq1}i_{d1}i_{q1}\right)
\] (33)

The diesel generator will operate with minimum load of 35% of the rated power. The alkaline electrolyzers are used as dump load. The electrolyzers are supplied by the surplus power, and then contribute to balance the load demand and power production.

2.4. Alkaline electrolyzer

The decomposition of water into hydrogen and oxygen can be obtained by passing a direct electric current (DC) between two electrodes separated by a membrane and containing an aqueous electrolyte with good ionic conductivity. The electrodes are immersed in an alkaline aqueous solution.

The electrolyzer model is composed of several modules (F. J. Pino et al., 2011). Powered by the DC electrical sources and pure water, an electrolyzer can effectively split water into hydrogen and oxygen. Since it is difficult to obtain analytically the inverse of the equation (34), linear models are used generally in literature (R. Takahashi et al. 2010).

In this paper, the electrolyzer model takes into account the ohmic resistances and cell overvoltage (equation 34) (O. Ulleberg, 1998).

\[
V_{cell} = E_0 + \frac{r_1 + r_2 T_{ele}}{A_{ele}} I_{ele} + s_0 \log \left( \frac{t_1 + t_2 / T_{ele} + t_3 / T_{ele}^2}{A_{ele}} + 1 \right)
\] (34)

\[
s_0 = s_1 + s_2 T_{ele} + s_3 T_{ele}^2
\] (35)
\( V_{rev} \) is the reversible voltage, \( r, s \) and \( t \) are the empirical parameters whose values are determined from experiments (N. Gyawali and Y. Oshsawa, 2010).

The electrolyzer’s voltage is expressed as:

\[
V_{ele} = N_c V_{cell}
\]  

(36)

\( V_{cell} \) is the voltage of electrolyzer cell and \( N_c \) is the number of cells of the electrolyzer.

3. Hybrid power system simulation results

The load’s power, diesel genset’s power and wind generators power are shown respectively in Fig. 8, Fig. 9 and Fig. 10. The diesel genset operates with minimum load of 35% of the rated power (Fig. 9). Three 80 kW alkaline electrolyzers are used as dump load. The surplus power is absorbed by the electrolyzers (Fig. 11, Fig. 12, Fig. 13) which contribute to balance the load demand and power production (Fig. 14). Electrolyzers contribute to maintain the frequency of the autonomous power system (Fig. 15).

Conclusion

This chapter is devoted to a large scale wind diesel Hybrid Power System (HPS). It presents theoretical analysis, modelling and control of Wind Energy Conversion Systems (WECS) connected to an autonomous power system with hydrogen storage. The wind generator under study is a Doubly Fed Induction Generator (DFIG) type. The models of the main components (mainly wind turbine, generator, diesel generator, electrolyzer) are derived. Power transfer strategy in the interconnected system was presented. The effectiveness of the proposed control strategy was validated by simulation using Matlab/ Simulink/ SimPowerSystems environment.
