Chapter 16

Latin Hypercube Sampling

Jaroslav Menčík

Additional information is available at the end of the chapter

http://dx.doi.org/10.5772/62370

Abstract

The simultaneous influence of several random quantities can be studied by the Latin hypercube sampling method (LHS). The values of distribution functions of each quantity are distributed uniformly in the interval (0; 1) and these values of all variables are randomly combined. This method yields statistical characteristics with less simulation experiments than the Monte Carlo method. In this chapter, the creation of the randomized input values is explained.

**Keywords:** Probability, Monte Carlo method, Latin Hypercube Sampling, probabilistic transformation, randomization

The Monte Carlo method has two disadvantages. First, it usually needs a very high number of simulations. If the output quantity must be obtained by time-consuming numerical computations, the simulations can last a very long time, and the response surface method is not always usable. Second, it can happen that the generated random numbers of distribution function $F$ (which serves for the creation of random numbers with nonstandard distributions) are not distributed sufficiently and regularly in the definition interval (0; 1). Sometimes, more numbers are generated in one region than in others, and the generated quantity has thus somewhat different distribution than demanded. This problem can appear especially if the output function depends on many input variables.

A method called Latin Hypercube Sampling (LHS) removes this drawback. The basic idea of LHS is similar to the generation of random numbers via the inverse probabilistic transformation (3) and Figure 2 shown in Chapter 15 [1, 2]. The difference is that LHS creates the values of $F$ not by generating random numbers dispersed in chaotic way in the interval (0; 1), but by assigning them certain fix values. The interval (0; 1) is divided into several layers of the same width, and the $x$ values are calculated via the inverse transformation ($F^{-1}$) for the $F$ values
corresponding to the center of each layer. With reasonably high number of layers (tens or hundreds), the created quantity \( x \) will have the proper probability distribution. This approach is called stratified sampling. If the output variable \( y \) depends on several input quantities, \( x_1, x_2, \ldots, x_m \), it is necessary that each quantity is assigned values of all layers and that the quantities and layers of individual variables are randomly combined. This is done by random assigning the order numbers of layers to the individual input quantities.

![Graph of F(x) and F(L2)](image)

**Figure 1.** Principle of the LHS method.

The procedure is as follows. The definition interval of the distribution function \( F \) of each of \( m \) variables is divided into \( N \) layers. \( N \) is the same for all variables, also corresponds to the number of trials (simulation experiments). In each trial, the order numbers of layers are assigned randomly to the individual variables \( (X_1, X_2, \ldots, X_m) \). In this way, various layers of the individual variables are always randomly combined. In practice, this is achieved by means of random numbers and their rank-ordering. Then, each input variable is assigned the value corresponding to the center of the pertinent layer of its distribution function.

The application is illustrated on a case with four random quantities \( (X_1, X_2, X_3, \text{ and } X_4) \) and the definition interval of \( F \) divided into five layers (Fig. 1). Only five layers are used here for simplicity; usually, several tens of layers are used. In our case, \( Y \) will be calculated for five combinations of the four input quantities. Thus, \( 5 \times 4 = 20 \) random numbers with uniform distribution in interval \( (0; 1) \) are generated (see the table in the left part of Fig. 2). Then, the layer numbers for variable \( X_1 \) (for example) for individual trials are assigned with respect to the order of random values (for \( X_1 \)) ranked by size from the maximum to minimum. Here, layer no. 3 (with the highest number 0.83) for the first trial, layer no. 1 for the second, no. 5 for the third, no. 2 for the fourth, and no. 4 for the fifth, corresponding to the numbers 0.56 - 0.25 - 0.83 - 0.17 and 0.30 in the column for \( X_1 \). Similar operations are done for each variable. Thus, in the first trial, variables \( X_1, X_2, X_3, \text{ and } X_4 \) are assigned the values corresponding to the second,
fourth, second, and fifth layers of their distribution functions, respectively. Inverse probabilistic transformation $F^{-1}$ is then used for the determination $X_1$ from $F_1$, etc.; see the table on the right. Now, the investigated quantity $Y = Y(X_1, X_2, X_3, X_4)$ is calculated five times. The obtained values $Y_1, Y_2, Y_3, Y_4$, and $Y_5$ can be used for the determination of statistical characteristics (mean, standard deviation,...).

Figure 2. LHS method: assignment of layers to individual variables and trials.

Usually, several tens or hundreds of trials are made, which enable the construction of distribution function $F(Y)$ and determination of the mean value, standard deviation, various quantiles, and other characteristics.
