Abstract

The laser ablation in liquid environment (LALE) technique is a straightforward experimental technique with few controllable parameters, capable to provide extreme pressure and temperature conditions during target ablation without the need for dedicated systems to provide those variables. Additionally, we can state that LALE can be considered a low-cost experimental technique, with few steps and a clean synthesis method, by which a wide variety of materials can be synthesized with high yield. The majority of studies published in the literature using this technique seem to be limited only to the synthesis of metal nanoparticles, metal oxides, nitrates and semiconducting. However, in order to extend the synthesis potential of this technique, in this chapter we are going to demonstrate that with the appropriate choice of reactants, solvent, target materials and the solid-liquid interface interactions we will be able to prepare more complex molecules such as carbonate compound Pb$_3$(CO$_3$)$_2$(OH)$_2$, metal-organic frameworks (MOFs), luminescent metal-organic frameworks (LMOFs), highly dispersed CdS quantum dots and magnetic materials. Also for each material synthesized, we are going to propose a mechanism to explain its preparation using the LALE technique.

Keywords: laser ablation in liquid, nonconventional synthesis, materials preparation, complex compounds, inorganic compound
1. Introduction

Searching the literature we can observe that there is a huge amount of techniques that can be used for material preparation. As a matter of fact, for each group of materials there is a specific route more suitable to be used. An interesting conclusion we can make is the fact that unusual properties obtained in a specific material is sometimes related to the selected preparation method. To be more specific, not only the method used but also the solvent, the concentration, the manner, or the sequence in which the reaction components are mixed make these characteristics more pronounced when we are taking into consideration the preparation of nanomaterials.

On the other hand, among several methods developed in the last decade for material preparation, it can be observed that one stands apart: the pulsed laser ablation technique (PLA). The reason seems to be the high potential presented by the laser-based material processing for the thin solid film preparation, nanocrystal growth, surface cleaning and microelectronic device fabrication [1–5]. The pulsed laser ablation of solid materials was initially carried out in a conventionally evacuated deposition chamber and the majority of the results have focused on pulsed laser deposition (PLD) of solid targets in vacuum and in a diluted gaseous ambient [6, 7].

Moreover, a slight modification of the PLD technique for materials preparation is the laser ablation in liquid environment (LALE). This technique has been extensively used at the beginning for the preparation of colloidal solution of metallic nanoparticles and subsequently as a successful technique for the fabrication of nanostructured metals oxide, nitrate and other materials of various compositions, morphologies and phases [8, 9]. Additionally, this technique nowadays can be considered a chemically clean and one-pot synthetic route by which a variety of functionalized new nanostructures can be prepared with a high yield of the final product without any by-products and, mostly, there is no need for further purification.

Compared with others techniques, LALE can be considered as a low cost experimental technique, which presents few controllable parameters and provides extreme experimental conditions of high temperature and pressure that favors the formation of unusual metastable phases. The technique consists of the interaction of a high-intense Laser pulse with a solid...
target immersed in a liquid solution as shown in Figure 1(a). In this case, both the ablation of the target material and the interaction of the laser beam with the solvent (Figure 1b) occur simultaneously. As a consequence, the plasma plume formed by the target ablation expands and is confined by the liquid. Some works indicated that the density of the ablated species is of the order of $10^{22} - 10^{23} \text{ cm}^{-3}$, the temperature could reach 4000–5000 K and the pressure is of the order of 10 GPa inside the plasma plume generated by the ablation in liquid [8]. According to Ogata and coworkers [10], interesting chemical reactions could take place at the interface between the plasma plume and the liquid, allowing the synthesis of a new chemical compound. Although this technique has proved to be an excellent route for material preparation, this methodology has been used mainly to obtain metal oxide, metals colloids, semiconductor and nitrites [11–17]. Therefore, it will be presented, in detail, the synthesis of five chemical compounds prepared by the LALE technique that had been prepared at the Solid State Laboratory of Federal University of Pernambuco in order to demonstrate the versatility of the laser ablation technique and also to convince the scientific community that this is a very powerful tool for the preparation of complex materials.

2. Experimental

Figure 1 shows the experimental set up used for all compounds preparation. For the target ablation, a second harmonic of a pulsed Nd:YAG laser (Spectra-Physics Quanta-Ray GCR-170 or a Quantel, model Brilliant B) is used, operating at 10 Hz with 8 ns of pulse width, with the beam focused on the target with a spot size of about 1 mm in diameter using a lens with a focal length of 50 mm. The synthesis processes differ from each other only on the Laser fluency used, ablation time, kind or type of target, solvent used and the proposed mechanism that explains its formation.

2.1. Synthesis of Pb$_3$(CO$_3$)$_2$(OH)$_2$

For the synthesis of the carbonate compound Pb$_3$(CO$_3$)$_2$(OH)$_2$, a target of solid Pb metal (99.5%, from America Elements) was used and ablated for 10 minutes with a pulsed Nd:YAG laser as shown in Figure 1. Finally, the products were centrifuged and collected. The solutions obtained, including sediments, were dropped and dried on glass substrates for sample characterization. For the purpose of comparing the results, three different laser fluencies on the solid target were used: 0.5, 1.0 and 2.0 J/cm$^2$ and in order to establish the mechanism for sample preparation, the ablation reaction was performed in methanol (Merck PA), ethanol (Kinetics PA), 1-propanol (Merck PA) and 1-butanol (Merck PA) [17, 18].

2.2. Synthesis of CdS quantum dots

In this case, the synthesis of the nanostructured CdS quantum dots was performed using a metal cadmium foil, which is 0.5 mm thick (99.99%) from Aldrich Company as a target for the Cd ion source production and thiosulfate and thioglycerol from Merck company as a sulfur source. The cadmium metal foil was washed with a mixture of H$_2$O:HNO$_3$ 1:1 (v/v) to remove
the oxide layer, followed by distilled water and acetone washing under ultrasound bath for 5 min.

The Cd foil was immersed in a Beaker (50 ml) filled with aqueous solution of thiosulfate (5, 7, 9, 12 and 15 mmols) and thioglycerol (5 mmols) and ablated for 5 min with the second harmonic order light pulse of a Nd:YAG laser. Soon after the ablation starts, the solution changes its color from transparent to yellow as an indicator that the reaction is taking place. Finally, the products were centrifuged and washed several times with acetone and the material was collected for characterization [19].

2.3. Synthesis of magnetic iron compounds

For the synthesis of magnetic nano- and micro-iron oxide particles, the solid iron targets were ablating immersed in an aqueous solution of basic pH. As a result of the iron ablation, we observed the formation of ions ferrate (VI), α-iron and the unusual form of iron oxides FeO. The aim of this study is to evaluate how the material contained in the plasma plume formed by the laser ablation of an iron target evolves into a medium of high pH and chemically reacts with the solution to form iron oxides. We also examined how the fluency of laser pulses applied to solid iron target surface influences the preparation process.

For this experiment, we used Fe plates that were chemically cleaned, washed with water and then subjected to ultrasonic bath in ethanol for 5 min. The ambient liquid used was a solution with a concentration of 1 molar sodium hydroxide in distilled water and measurements indicated that the pH of the solution was 14. The ALAL was performed with three laser beam fluency values, the materials prepared under these conditions were designated as Type1, Type2 and Type3 and Table 1 shows the synthesis parameters used for the preparation of these samples. All experiments were conducted at a temperature of 293 K and pressure of 1 atm. To minimize the number of variables in the preparation process, the same values for repetition rate of the laser pulses and the height of the liquid layer on the solid target (10 mm) were used, both for the volume to the liquid environment and for the laser ablation time at which the target has been subjected.

Table 1. Experimental parameters for ALAL of iron plates.

2.4. Synthesis of Cu₃(BTC)₂(H₂O)₃

For the synthesis of the Cu₃(BTC)₂ MOF, a Cu powder metal (99.5%) was used as a target for the ablation dispersed in a solution of a DMF:H₂O (1:1) containing the organic linker benzene 1,3,5 benzene tricarboxilic acid and NaNO₃ as a hydroxyl radicals (•OH) precursor. The target
was ablated for 60 min under magnet stirring with the second harmonic of a pulsed Nd:YAG laser. Soon after the ablation starts, the solution changes its color and a blue precipitate occurs. Finally, the products were centrifuged and collected for sample characterization [20].

2.5. Synthesis of Eu(TMA)(H$_2$O)$_4$

For the synthesis of the microstructured luminescent MOF Eu(TMA)(H$_2$O)$_4$, instead of using metal or metal powder as a target, europium oxide powder (Eu$_2$O$_3$) (99.99%, Sigma Aldrich) was used as a target. In this case, the powder was dispersed in a solution of DMF/H$_2$O (1:1), containing the organic linker Trimesic acid (TMA) and sodium nitrate (NaNO$_3$) under a magnetic stirring. As it is shown in Figure 1, the target was irradiated for 60 min with the second harmonic ($\lambda = 532$ nm) of a pulsed Nd:YAG laser. It is interesting to notice that as the ablation starts, the solution changes its optical characteristic, with the initial transparent solution becoming milk-like white as the reaction continues and finally a white precipitate occurs. In order to characterize the materials, the products were centrifuged, washed with hot water several times and dried under vacuum. Sample characterization allows us to conclude that the reaction yield is of the order of 70%. Compared with the literature results for different synthesis method we can conclude that it is a good yield [21–23].

3. Material characterization

Spectroscopic characterization in the UV-visible and infrared region was performed with an Ocean Optics model 2000 spectrophotometer and with a FTIR/FT-NIR Spectrometer model Spectrum 400 Perkin Elmer, respectively, while room temperature photoluminescence (PL) was measured in Ocean optics model QE65000 spectrophotometer with the sample been exited with a N$_2$ laser or in a Horiba Jobin Yvon spectrofluorometer model Fluorolog-3 FL3-22 using a 450-W xenon short-arc lamp light as the excitation source. The luminescence quantum yields measurements were recorded with a Horiba Jobin Yvon spectrofluorometer using an integrating sphere model F-3018.

The particle morphology and structure was characterized by transmission electron microscope (TEM) and X-ray diffraction measurement, using a Tecnai 20 transmission electron microscope operating with an accelerating voltage of 200 KV and a Rigaku diffractometer model DMAX 2400, using Cu K$_\alpha$ radiation ($\lambda = 0.154$ nm) at a scanning speed of 0.1° s$^{-1}$ in the range of 2$\theta$ = 10–60° with a step 0.02°, respectively. The sample for the TEM measurements was diluted and dropped onto a carbon-covered 200-mesh copper grid followed by natural evaporation of the solvent.

4. Results and discussion

The first example of a compound synthesized by LALE technique shown in this chapter is the synthesis of hydrocerussite Pb$_3$(CO$_3$)$_2$(OH)$_2$, a quite rare mineral in nature that is found in soil.
only in small quantities. It consists of basic lead carbonate with a trigonal crystalline structure [24]. Although it is rare in nature, it was extensively synthesized and used not only as a cosmetic or in religious and medical practices [25] from Ancient Egypt to the Greco-Roman period [26] but also as a white pigment in easel painting [27] from the Renaissance to the end of the nineteenth century. More recently, it has been playing a significant role in geology, in environmental issues [28, 29], applied as a polymer stabilizer [30] and has been extensively investigated in the lead acid battery industry because its presence in battery plates increases the resistivity of the electrolyte [31].

The ablation of a Pb target in methanol or ethanol results in a whitish powder precipitation while a grayish color solution was obtained when 1-propanol or 1-butanol was used. The mechanism proposed to explain the whitish precipitated material is demonstrated in the scheme below, in which the ablation of the Pb target in a solution produces Pb atoms, ions and Pb particles that become dispersed in the liquid environment and subsequently interact with absorbed O\(_2\) to form the lead oxide PbO.

The decomposition of methanol into CO\(_2\) and H\(_2\)O is catalyzed by the ablated metal that remains in solution [32–34]. The remaining CO\(_2\) reacts with PbO to form the hydrocerussite compound.

\[
Pb_{(\text{solid})} + h\nu + O_2 \rightarrow n\text{Pb} + \text{Pb}^{+m} + \text{PbO} \quad (1)
\]

\[
\text{CH}_3\text{OH} + O_2 \xrightarrow{h\nu + n\text{Pb}^0} \text{CO}_2 + \text{H}_2 + \text{H}_2\text{O} \quad (2)
\]

\[
3\text{PbO} + \text{CO}_2 + \text{H}_2 \rightarrow \text{Pb}_2(\text{CO}_3)(\text{OH})_2 \quad (3)
\]

In order to prove the efficacy of the mechanism proposed in Figure 2, we present the X-ray diffraction analysis of the samples prepared in methanol, ethanol 1-propanol and 1-butanol. For the samples prepared in methanol and ethanol the diffraction peaks correspond to the crystalline planes of the trigonal crystalline structure of the hydrocerussite reported on JCPDS card 130131. While for the Pb target ablated in 1-propanol and 1-butanol it is observed that diffraction peaks refer to the hydrocerussite and the crystalline planes of the cubic FCC of metallic phase lead to a structure in agreement with the reported on JCPDS card 040686. It is interesting to notice that the metal became the major phase for the Pb target ablated in 1-butanol.

In conclusion, we may say that if we carefully choose the solvent, we are able to decide which material will be synthesized. Hydrocerussite is obtained when the Pb target is ablated in ethanol and methanol solution whereas hydrocerussite and Pb metal particles are obtained from the solvent 1-propanol and 1-butanol and the metallic phase is more abundant in 1-butanol.
Figure 2. XRD patterns recorded for the samples PbMet-A, PbEtha, PbPro and PbBut. The crystalline phases and main crystalline planes associated with each phase are also shown.

As a matter of fact, several metal nanoparticles such as cobalt, nickel, silver, copper, palladium and semiconductor quantum dots (QDots) [35–39] have been obtained using the reducing power of alcohols with large carbon chains.

Figure 3 shows the SEM characterization for the sample prepared in methanol and it is observed that a hexagonal structure was obtained with average widths of 1.0 ± 0.3 µm and an average thickness of 80 ± 20 nm. This result is similar to the morphology results found in the literature for hydrocerussite [24, 40].

Figure 3. SEM image for PbMet-A sample as made.

The second example of a chemical compound prepared by LALE technique is the synthesis of II–VI semiconductor quantum dots (QDots). The reason for that interest seems to be the high technological potential that these materials present in several areas such as optic, electronic, catalyst application, solar photovoltaic cells, nanobar codes, field effect transistors, light emitting diodes and in vivo biomedical detection fluorescent tags in biology and the development of chemical and biological sensors [41–47]. Concerning to the CdS preparation, the
synthesis consists of the ablation of cadmium foil in the thiosulfate and thioglycerol solution for 5 minutes. As a consequence, a highly stable colloidal solution is obtained and presents a strong yellow fluorescence peak at 590 nm that can be seen by the naked eye when the sample is excited with UV light at 365 nm as shown in Figure 4.

These results allow us to conclude that quantum confinement is observed since the absorption bands of the colloidal solution suffer a blue shift to 360 nm when compared with CdS bulk emission at 515 nm [47].

The mechanism proposed to explain the CdS quantum dots formation is shown in Eqs. (4)–(6), where the Cd target is ablated-producing ionizing species together with the action of thioglycerol as a catalyst for the thiosulfate hydrolysis [48, 49], which results in situ formation of sulfide ion (S\(^2^-\)) and consequently the formation of CdS particle.

\[
S_2O_3^{2-} + H_2O + TG \rightarrow SO_4^{2-} + H_2S
\]  

\[
(m + n)Cd_{(s)} \xrightarrow{hv} nCd_{(s)} + mCd^{2+} + 2me
\]
Additionally, it can be seen that, in this process, thioglycerol is used as a hydrolyzing agent for thiosulfate (1) and as stabilizing agent for the nanoparticles.

From the analysis of the absorption spectra we found that the band gap of the CdS semiconductor is of the order of 3.1 eV and using the effective mass approximation method developed by Burs [50], we can estimate that the optical particle size is of the order of 3.2 nm. From the analysis of X-ray diffraction measurement of Figure 5 and the comparison with the JCPDS card file number 10-454, we conclude that the CdS particle crystallize in a zinc blende structure and from the broadening of the diffraction peak we can see that the peaks present a very broad distribution indicating the presence of a very small crystallite size.

Figure 5. (a) X-ray diffraction of quantum dot CdS and (b) plot Williamson-Hall for crystallite size determination.

Using the Williamson-Hall method for the diffraction peaks analysis, we found that the crystallite size is of the order of 2.2 nm. This result is slightly smaller than those calculated by optics method. However, it indicates that we were successful in preparing very small CdS quantum dots particle. It is interesting to mention that the CdS nanocrystals possess the cubic space group, instead of the hexagonal wurtzite structure which is thermodynamically more stable. This probably could be attributed to the nonconventional chemical reaction condition of high pressures and temperatures which favors the occurrence of chemical processes in nonequilibrium conditions and the formation of materials with metastable configurations [51, 52].

The third example is the synthesis of magnetic iron samples. In this study, all prepared materials were dispersed or stabilized in liquid environment after synthesis. The samples were further characterized in a liquid phase by absorption spectroscopy in the ultraviolet and visible region. The materials of samples Type1, Type2 and Type3 were separated from the NaOH precursor solution by centrifugation and also washed in distilled water. A fraction of the prepared samples was precipitated on glass plates for the scanning electron microscopy.
characterization, while another fraction of the samples was pulverized and subjected to X-ray diffraction, infrared spectroscopy and magnetic measurement. Figure 6 shows UV-Vis spectra for the precursor solution of sodium hydroxide and for the resulting solutions of the preparation process for samples 1, 2 and 3.

![UV-Vis spectra of samples Type1, Type2 and Type3 and of precursor solution.](image)

Figure 6. UV-Vis spectra of samples Type1, Type2 and Type3 and of precursor solution.

It is possible to see in Figure 6 that the spectra of samples 1, 2 and 3 have three additional absorption bands when compared with the spectrum of the precursor solution of NaOH. These absorption bands are related to the presence of the dispersed material prepared in the solution resulting from laser ablation. It is also observed that the absorption bands were more intense for the materials prepared with the application of higher fluencies on the solid target. This fact indicates that the higher the fluency used in experiments, the higher is the amount of material obtained and dispersed in solution per unit time. This result is consistent with the UV-Vis spectrum for iron and iron oxide nanoparticles in aqueous solution. The absorption bands with maxima at 216 and 268 nm may be associated with iron nanoparticles, while the band located at 350 nm is likely due to other phases present in the samples [53].

From the analysis of the results obtained by ultraviolet and visible spectroscopy, FTIR, scanning electron microscopy, X-ray diffraction and magnetometry, it allowed us to conclude that all samples (named as Type1, Type2 and Type3) prepared, under three different experimental conditions, are nanostructured and formed respectively by: Type1 sample crystalline phases regarding the presence iron (Fe), iron oxide (FeO), sodium ferrate (V) (NaFeO₃), sodium ferrate (VI) (Na₂FeO₄) and sodium hydroxide (NaOH); Type2 sample, Fe, FeO, Na₂FeO₄ and NaOH; Type3 sample, Fe and FeO. The metastable FeO phase is especially interesting because it is generally prepared only at high temperatures and by rapid cooling process [51].
The prepared samples show magnetic properties, with the Fe and FeO (Type3) having the most intense magnetic response, whereas the Type1 sample shows intermediate intensity response and Type2 material shows the less intense magnetization response. Some modification of the synthesis conditions used in these experiments resulted in the preparation of ferrate sodium compound (V) (NaFeO$_{3}$) and sodium ferrate (VI) (Na$_2$FeO$_{4}$). In these compounds the iron atoms have a high oxidation number lying the state Fe$^{5+}$ and Fe$^{6+}$. The FeO$_{3}^{-1}$ and FeO$_{4}^{-2}$ ferrate ions present high potential for technological application in several scientific areas, such as in the degradation of environmental pollutants and as disinfectants [54]. Furthermore, recent studies indicate that FeO$_{4}^{-2}$ ions have promising applications as electrolytes materials in rechargeable batteries [55].

Thus, the laser ablation of iron targets in sodium hydroxide solution presents itself as a new method for the preparation of sodium ferrate, enabling control of the properties of materials prepared by tuning the fluency of laser pulses. To the best of our knowledge, obtaining sodium ferrate by ALAL and obtaining results regarding the control of crystallinity and magnetization of such samples by ALAL are unprecedented in the literature.

The scanning electron microscopy performed on samples Type1, Type2 and Type3 shows that these materials consist of particles of approximate spherical shape and with different size distribution for each type of material. Figure 7(a) shows the Type1 material consists of spherical particles with an average size of 170 nm that are both dispersed and isolated on the substrate or agglomerated as structures formed by larger particle clusters. Figure 7(b) shows that the Type2 material has particles with spherical shape and average size of the order of 0.7 µm and it seems that the distribution of particle sizes in this sample is wider than that presented by the sample Type1. Figure 7(c) shows that the SEM image is composed of agglomerated particles of 50 nm in size, where it is also possible to visualize a few micron size particles.

Figure 7. Image of SEM for: (a) Type1 sample; (b) Type2 sample; (c) Type3 sample.

The SEM shown in Figure 7(a)–(c) allowed to estimate the average size and average standard deviation for the size distribution of the particles in the samples Type1, Type2 and Type3. The results of these measurements are shown in Table 2.

These results indicate that the structural properties of the obtained materials are susceptible to the fluency of the laser beam used in the preparation procedure and therefore it is possible to control the size and size distribution of the sample by controlling the fluency. This behavior
may be related to the photolysis promoted by the laser beam onto the prepared particles and increases the ablated material density in the plasma plume. These two effects increase when the fluency is increased and their joint action could explain the observed results: photolysis tends to decrease the size of the particles while high density plume favors to obtain larger particles.

Table 2. Estimate of the average size for Type1, Type2 and Type3 samples.

The X-ray diffraction was used for the identification and structural characterization of the prepared materials. The XRD patterns obtained for Type1, Type2 and Type3 samples are shown in Figure 8, where they are also indicating crystalline phases present in the samples that were identified by comparison with the software database PCPDF WIN of JCPDS-ICCD. Analyzing the XRD patterns of the samples and correlating the maximum diffracted intensity with the major peaks of diffraction patterns in JCPDS database is verified that prepared under Type1 experimental conditions is formed by crystalline phases regarding the presence of iron (Fe), iron oxide (FeO), sodium ferrate (V) (NaFeO$_3$), sodium ferrate (VI) (Na$_2$FeO$_4$) and sodium hydroxide (NaOH). The Type2 sample shows evidence of the presence of Fe, FeO, Na$_2$FeO$_4$, and NaOH, while in Type3 sample, the presence of Fe and FeO phases was only found. It is
interesting to notice that the FeO phase is metastable and can be prepared only at high
temperatures and by a fast cooling process [51].

Figure 7 shows that when the fluency applied to the target solid surface increases, it is possible
to observe progressively reducing on the crystallinity of the prepared samples. Clearly, the
Type1 sample with a fluency of 0.5 J/cm² has well-defined crystalline phases, while Type3
sample prepared using 4.0 J/cm² fluency is majorly amorphous. This behavior can be explained
by considering the rapid cooling effect of the liquid environment of the plasma plume. The
temperature of the ablated material in the plume plasma should increase proportionally to the
fluency of laser pulses; on the other hand, the cooling capacity of the liquid environment
basically depends on the temperature and the volume of liquid used. In this way, the higher
the fluency used, the higher the cooling rate due to liquid environment, because greater will
be the temperature variation during the short time cooling.

The proposed cooling model can explain the crystalline dependence of the material obtained
with the fluency of the laser beam used in the preparation process. The fluency values used
during the preparation of the samples Type1, Type2 and Type3 correspond to cooling rates \( T_1 \),
\( T_2 \) and \( T_3 \), and \( T_3 > T_2 > T_1 \). Although the specific time (time per mass) available for crystallization
of the ablated material is higher in Type1 than in Type2, this in turn has the time available for
crystallization higher than the Type3 sample. The short crystallization time for Type2 and
Type3 samples inhibits the formation of well-defined crystalline phases, leaving the samples
Type2 and Type3 less crystalline and substantially amorphous.

![Figure 9. IR transmittance spectrum.](image)
Figure 9 shows the infrared transmission spectra (IR spectra) for the materials prepared. It is observed that most of the absorption modes of Type1 and Type2 materials coincide, although it does not happen for sample Type3. This indicates that the composition and chemical structure of Type1 and Type2 samples are similar, while they differ from the composition and structure presented by the sample Type3. Comparing the IR spectra obtained from data available in [56] literature it was possible to verify the presence of Na$_2$FeO$_4$ in Type1 and Type2 samples by identifying active stretching and vibration modes relating to the tetrahedral distribution of four oxygens around the Fe ion (VI). The modes for the Na$_2$FeO$_4$ are not displayed in the IR spectrum of Type3 sample confirming the assumption that Type1 and Type2 samples are chemically similar and that the composition of the sample differs from that presented by Type3. The presence of FeO in all samples was attributed comparing it with data from the literature [57]. The IR spectroscopic analysis results corroborate the X-ray diffraction.

Figure 10 shows the magnetization curves measured as a function of applied magnetic field for the samples Type1, Type2 and Type3. The analysis of magnetization curves indicates that all samples exhibit hysteresis, thus being classified as ferromagnetic, although it is noticed that the magnetic response is different for each sample. When the materials are subjected to a field of the same intensity, Type3 material has higher magnetization, this value is higher than the Type1 and Type2 samples and the Type2 sample has the lowest value of magnetization.

The magnetic response of samples can be related to the size of their structures. It was observed in this experiment that for the same value of applied magnetic field, the magnetization of the module $M(H)$ of Type1, Type2 and Type3 samples increases with decreasing diameter, $D$, of the particles in the sample. In other words, it was found that $M(H)_{\text{Type3}} > M(H)_{\text{Type1}} > M(H)_{\text{Type2}}$. 

![Figure 10. Magnetization per unit mass as a function of applied magnetic field.](image-url)
while $D_{\text{Type3}} > D_{\text{Type1}} > D_{\text{Type2}}$. We observed size effects on the magnetic response of the samples, possibly related to the size and presence of magnetic monodomain within the particles of a smaller size, while larger particles should contain several oriented monodomain randomly causing a less effective magnetic response.

We can also qualitatively relate the magnetic behavior of the samples to their chemical composition: The Type1 sample is formed by phases Fe, FeO, NaFeO$_2$, Na$_2$FeO$_4$, and NaOH, while Type2 sample is formed by Fe, FeO, Na$_2$FeO$_4$, and NaOH and Type3 by Fe and FeO. It is known that unpaired electrons in the atomic orbitals of a material are responsible for their magnetic properties and the greater the number of unpaired electrons will be, the higher its magnetization per unit mass. Iron atoms in Fe and FeO phases are respectively 4 and 4 unpaired electrons. However, the phase NaFeO$_2$ the iron atoms present only 3 unpaired electrons and Na$_2$FeO$_4$ phase has unpaired electrons. Since the magnetization was measured by mass, this argument justified the reason that Type3 sample, composed of Fe and FeO, is the most intense magnetic response. The Type1 material its intermediate intensity response and the Type2 material is the less intense magnetization ($M(H)_{\text{Type3}} > M(H)_{\text{Type1}} > M(H)_{\text{Type2}}$).

We can summarize that the preparation of micro- and nanostructured magnetic particles through ALAL iron targets of sodium hydroxide 1 M was successfully obtained. The results demonstrate that structural and magnetic properties of the materials prepared are influenced by the applied laser beam fluency during the ablation process. Specifically it was found that the fluency can be used to control the size distribution of structures present in the sample as well as controlling the magnetization and the crystallinity of the material prepared.

The fourth and fifth examples are the synthesis of the MOFs and LMOFS. For the synthesis of metal organic framework, we have developed two procedures: for the Cu$_3$(BTC)$_2$(H$_2$O)$_3$ preparation, a copper metal powder was used as a target, while for the synthesis of the luminescent MOF Eu(TMA)(H$_2$O)$_4$ a metal oxide powder was used as a target instead.

We chose the metal organic frameworks (MOFs) materials as the next example for the fact that this structure are quite complex and consist of a three-dimensional (3D) metal coordination network formed by metal ions or clusters linked together by organic bridging ligands. Consequently, this material presents high surface area, uniform small porous architecture [58], open metal sites [59], possibility of structure modification through postsynthesis functionalization routes [60], that together with luminescent proprieties make MOFs materials promising for several applications such as gas storage, gas separation, heterogeneous catalysis [61, 62], sensing devices [63, 64], ion exchange [65, 66], optoelectronics [67, 68] and efficient phosphors for displays and lighting [69]. Regarding to the sample preparation, almost all methods used for MOFs preparation are time consuming, except for the microwave-assisted processes and therefore new methods should be developed in order to overcome this advantage.

The main difference between the methods applied before for the materials preparation is the fact that for the Cu$_3$(BTC)$_2$(H$_2$O)$_3$ preparation, copper metal powder dispersed in liquid medium was used as a target, whereas to synthesize Eu(BTC)(H$_2$O)$_4$ europium oxide was used as a target. In both syntheses, magnetic stirring was used to homogenize the suspension in a
solution of trimesic acid dissolved in water and DMF. In Cu(BTC)$_2$(H$_2$O)$_3$ case, NaNO$_3$ was also used as oxidizing agent.

To explain the formation of Cu$_2$(BTC)$_2$(H$_2$O)$_3$, the mechanism proposed consists of a combination of two simultaneous processes. The first step involves the ablation of the metal surface, producing the ejection of the plume containing Cu$^0$ and metal ion Cu$^{1+}$ and Cu$^{2+}$ and also the photochemical decomposition of nitrate ions, that results in hydroxyl radicals (•OH) production, which in turn results in the increase of the amount of Cu$^{2+}$. Finally, the Cu$^{2+}$ reacts with the BTC to form the Cu$_3$(BTC)$_2$(H$_2$O)$_3$ framework, as shown in Eq. (7)–(12).

$$\text{Cu}_2^0 + h\nu \xrightarrow{\text{HDMF}^+ \text{BTC}^{1+} \text{NO}_3^-} \text{Cu}_2^0 + \text{Cu}_1^{1+} + \text{Cu}_1^{2+}$$ (7)

$$\text{NO}_3^- + h\nu \xrightarrow{\text{HDMF}^+ \text{BTC}^{1+} \text{NO}_3^-} \text{NO}_2^-(g) + \text{O}_2(h\nu)$$ (8)

$$\text{O}_2^- + 2\text{H}_2\text{O}(l) \xrightarrow{\text{HDMF}^+ \text{BTC}^{1+} \text{NO}_3^-} 2\text{OH}^-(aq) + 2\text{H}_2\text{O}(l)$$ (9)

$$2\text{OH}^- \xrightarrow{\text{DMF} \text{BTC}^{1+} \text{NO}_3^-} \text{H}_2\text{O}(l) + [\text{O}]$$ (10)

$$\text{Cu}_2^0 + [\text{O}] \xrightarrow{\text{DMF} \text{BTC}^{1+} \text{NO}_3^-} 3\text{Cu}_2^{2+} + \text{H}_2\text{O}(l)$$ (11)

$$3\text{Cu}_2^{2+} + 2\text{BTC}^{3-} \xrightarrow{\text{DMF} \text{O}_3^-} \text{Cu}_3(\text{BTC})_2(\text{H}_2\text{O})_3 + 4\text{H}_2\text{O}(l)$$ (12)

Figure 11. X-ray diffraction patterns (left) and FT-IR analysis (right) of [Cu$_3$(BTC)$_2$]-MOF prepared by laser ablation techniques at room temperature.
Figures 11 and 12 show the results of X-ray diffraction, infrared and scanning electron microscopy, which confirm that Cu$_2$(BTC)$_2$(H$_2$O)$_3$ MOFs has been successively prepared [20]. For the Eu(BTC)(H$_2$O)$_6$ preparation, it is noticed that the ablation of europium oxide (Eu$_2$O$_3$) make available Eu$^{3+}$ ions in solution, which reacts with BTC molecules to form a luminescent network as shown in Figure 13. Figure 14 shows the structural and spectroscopic characterization of the obtained compound, thus from the X-ray diffraction results we can conclude that the obtained LMOFs presents highly crystallinity with diffraction peaks isomorphic with Eu(BTC)(H$_2$O)$_6$. The FTIR analysis shows the disappearance of the carboxyl group in 1721 cm$^{-1}$ and the appearance of the modes in 1404 and 1275 cm$^{-1}$, strongly suggesting that the Eu$^{3+}$ ion is coordinated with the carbonyl group. Finally, the emission analysis shows that the compound exhibits an intense luminescence in the red region of the visible spectra $\lambda = 611$ nm, characteristic $^5D_0-^7F_2$ transition of Eu$^{3+}$ ions when irradiated with UV light at $\lambda = 254$ nm, with a quantum efficiency of 10.8% and life time of 0.26 ms.

Figure 12. Morphologic analysis of Cu$_2$(BTC)$_2$(H$_2$O) crystals prepared by the laser ablation technique as a function of the ablation time for: (a) 60 min, (b) 90 min.

Figure 13. SEM image of Eu(TMA)(H$_2$O)$_4$ and a photograph under UV excitation $\lambda = 254$ nm.
From the results above, we conclude that we have succeeded in synthesizing a three-dimensional networks Eu(TMA)(H₂O)₆ and Cu₃(BTC)₂(H₂O)₂ producing, for the first time, a metal-organic framework by laser ablation in liquid, wherein both obtained materials were crystalline and with well-defined morphology. Comparing with the conventional method, it is observed that this new synthesis route has the advantage of being a one-step synthesis, which allows obtaining submicromaterial with a high yield [21].

5. Conclusions

We have successfully developed a new technique for the synthesis of micro- and nanostructured materials using laser ablation in liquid environment, which consists of the combination of the target ablation in a liquid environment together with the photo physical or chemical decomposition of the solvent. With these method, several compounds, such as Cu₃(BTC)₂(H₂O)₂, Eu(TMA)(H₂O)₆, CdS quantum dots and magnetic materials such as Fe, FeO, NaFeO₃, Na₂FeO₄ have been prepared.

For each material prepared above, we observed that there was a different set of synthesis parameter to be adjusted in order to obtain the desired material. However, when compared with the conventional methods of synthesis, we can see that laser ablation in liquid is a straightforward technique with few adjustable parameter that allowed materials to be prepared with a high yield. As a matter of fact, with these examples we feel confident to propose this technique as the next-generation tool for the materials preparation.
