Usefulness of Cone Beam Computed Tomography for the Diagnosis and Treatment of Oral and Maxillofacial Pathology

Márcio Diniz-Freitas, Javier Fernández-Feijoo, Lucía García-Caballero, Maite Abeleira, Mercedes Outumuro, Jacobo Limeres-Pose and Pedro Diz-Díos

Abstract

Three-dimensional (3D) evaluation of oral and maxillofacial pathology, in comparison with two-dimensional (2D) radiological studies, offers many advantages that can assist in the diagnostic and in the preoperative evaluation of certain lesions and conditions of the jaws, reducing the risk of intraoperative and postoperative complications. The introduction of cone beam computed tomography (CBCT) represents an important technological advance in the context of oral and maxillofacial radiology as it permits the acquisition of high-quality 3D images and dynamic navigation over an area of interest in real time, with a short scan time and lower dose of radiation than conventional computed tomography (CT). The initial indications for CBCT have been extended by the progressive addition of new ones such as evaluation of the extent of osteonecrotic lesions of the jaw due to bisphosphonates, preoperative staging of oral cancer, and planning reconstructive surgery. As a consequence, this radiological technique represents an interesting complement to conventional radiology in those clinical situations in which 3D imaging can facilitate diagnosis and/or treatment.

Keywords: cone beam computed tomography, oral maxillofacial radiology, oral maxillofacial pathology
1. Introduction

Radiological evaluation of the size of a lesion, its density, thickness of the adjacent bone, and distance from anatomically nearby structures can assist in the diagnostic and in the preoperative evaluation of certain lesions and conditions of the jaws, reduce the risk of intraoperative and postoperative complications, and reduce surgical stress on the surgeon [1]. However, although two-dimensional (2D) radiological studies provide relevant information, in many situations they have limitations, such as indicating the location and size of a lesion in the buccolingual plane, showing characteristics of the surface (smooth or rough), and demonstrating changes that develop over time in order to evaluate progression of the lesion. As a consequence, three-dimensional (3D) studies are valuable in order to improve the diagnosis and treatment of these lesions.

Cone beam computed tomography (CBCT), also known as digital volumetric tomography (DVT) [2], volumetric computed tomography (VCT), or cone beam three-dimensional imaging (CB3D) [3], is a relatively new technology in the field of oral and maxillofacial radiology, but it is rapidly becoming established as the radiological technique of choice in numerous clinical situations [4]. CBCT enables a large quantity of data to be acquired with a short scan time and low dose of radiation compared with conventional computed tomography (CT). CBCT uses a conical X-ray beam (in contrast to the fan beam of conventional CT) and a special detector that, depending on the technology developed by the manufacturers, may be an image intensifier tube or an amorphous silicon flat-panel detector [4]. The X-ray source and reciprocal detector rotate synchronously around the head of the patient, in a single scan. Single projection images, known as “basis” images, are acquired at predetermined degree intervals. Software programs incorporating back-filtered projection are applied to the series of base images to generate a 3D volumetric data set, creating a spherical or a cylindrical volume called the “field of view” (FOV), which can be used to provide primary reconstruction images in three orthogonal planes (axial, sagittal, and coronal) [5].

The objective of this chapter is to provide a brief review of this new technology, its advantages and disadvantages, and its possible applications in the area of oral and maxillofacial pathology.

2. Clinical applications in dentistry

One of the main indications for CBCT is to determine bone availability for implant surgery [6]. However, the usefulness of CBCT imaging of the oral and maxillofacial region is continually increasing. Particularly useful indications include the diagnosis of bone disease (including maxillofacial fractures and deformities), preoperative evaluation of dental impaction, study of the temporomandibular joint, 3D cephalometric analysis in orthodontic practice, and diagnosis and surgical simulation in orthognathic surgery and in patients with cleft palate [7].

There now follows a summary of the most important studies on the use of CBCT in oral and maxillofacial pathology.
2.1. Disorders of tooth eruption

An important clinical application of CBCT is the diagnosis and planning of treatment for tooth eruption alterations. In this field, CBCT provides multiplanar visualization of the position of the tooth and its relationship with neighboring anatomical structures, as well as the presence of associated conditions, such as cystic degeneration of the dental follicle and root reabsorption of adjacent teeth, all of which are important factors in the therapeutic decision-taking process.

2.1.1. Dental inclusions

The extraction of impacted third molars is a common procedure in dental practice. In the majority of cases, it is a simple procedure with a minimal risk of damage to adjacent structures; however, in some cases, there is an intimate relationship between the roots of the mandibular third molars and the mandibular canal or the lingual cortical plate of the mandible, making it important to evaluate the topographical relationship between the third molar and these structures (Figure 1). Other characteristics that must be evaluated preoperatively are

![Figure 1. Inferior left third molar inclusion. (a) Detail of the panoramic reconstruction on CBCT in which the close relationship with the inferior alveolar nerve (IAN) canal (continuous line) is observed. (b) Cross-sectional images showing the three-dimensional location of the unerupted tooth and its relationship with the IAN (dark point). (c) Preoperative planning of surgical exodontia based on three-dimensional reconstruction (CS3D Imaging, CareStream, Rochester, NY).](http://dx.doi.org/10.5772/intechopen.68313)
angulation with respect to the sagittal plane, buccolingual inclination, size and shape of the crown, and the presence of local lesions. With respect to the roots of the tooth, the most important characteristic is their relationship with the mandibular canal, though it is also important to determine factors such as the number and shape of the roots and their stage of development in order to predict surgical difficulty [8, 9]. Oral and maxillofacial surgeons tend to use panoramic radiographs for evaluation of the morphology of impacted third molars and their relationship with the mandibular canal [10]. A number of radiological criteria suggestive of an intimate relationship between these two structures have been described in the literature. Sedaghatfar et al. [11] found that darkening of the root, interruption of the radiopaque lines that represent the roof and floor of the mandibular canal, divergence of the mandibular canal, and narrowing of the root on the panoramic radiograph were significantly associated with exposure of the inferior alveolar nerve after extraction of the mandibular third molars. Tantanapornkul et al. [12] found that these four criteria used independently were able to predict exposure of the nerve packet after third molars extraction, but in the multivariate analysis only interruption of the wall of the canal predicted nerve exposure. When the findings on the panoramic radiograph suggest an intimate relationship between the impacted tooth and the mandibular canal, some authors recommend complementary studies with CT or CBCT [13]. Using CBCT, Tantanapornkul et al. [12] found a sensitivity of 93% and a specificity of 77% for the prediction of inferior alveolar nerve exposure after third molar extraction, improving on the results obtained with panoramic radiographs. Exposure of the nerve correlated significantly with the presence of altered sensitivity in the postoperative follow-up. Recent studies based on images obtained by CBCT have shown that darkening of the root observed on the panoramic radiograph is more closely related with a reduction in the thickness or perforation of the lingual cortical plate than with the presence of an intimate relationship between the third molar and the mandibular canal. Thinning or perforation of the lingual cortical plate was confirmed on CBCT in 80% of cases in which darkening of the root was observed on panoramic radiograph [14]. When compared to a combination of 2D radiographs (panoramic radiography and cephalometric radiography), CBCT showed a higher detection quality of the relationship between the mandibular canal and the root tips of the third molars [15]. In addition, it has also been shown that CBCT is able to identify accessory roots and apical anomalies/curvatures not visible in the panoramic radiography [16].

Although two-dimensional imaging (panoramic and periapical radiography) is sufficient in most cases prior to the extraction of the lower third molars, CBCT may be indicated in cases where the two-dimensional image suggests one or more signs of close contact relationship between the third molar and the IDN, and if it is believed that the CBCT will change the treatment plan or the patient’s prognosis [17].

With respect to the maxillary third molars, CBCT can be used to evaluate the relationship between the roots and the floor of the maxillary sinus [18] (Figure 2). Another advantage of CBCT in the preoperative evaluation of third molar surgery is the possibility of significantly decreasing the surgeon’s level of stress in complex cases and reducing the duration of surgery.

The second most common dental impaction after the third molars is the maxillary canine, with a prevalence that varies between 1 and 2.5% [19]. Due to their functional and esthetic
relevance, the main objective in the treatment of impacted canines is their repositioning in the dental arch. Their 3D localization (Figure 3) is therefore important both for diagnosis and for the surgical-orthodontic management; this localization can be particularly difficult to explore with conventional radiological methods due to overlying anatomical structures [20]. CBCT can provide additional data not available with conventional 2D studies, such as the size of the follicle, the degree of inclination of the long axis of the tooth, facial-palatal position, the quantity of bone covering the tooth, the proximity and reabsorption of adjacent roots, and the stage of development of the tooth [21]. There are reports of the use of CBCT in the management of both maxillary- and mandibular-impacted canines [22]. Liu et al. [23] used CBCT to study the position and angulation of 210 impacted maxillary canines, the presence of reabsorption of the adjacent incisors, and the thickness of the dental follicle. These authors recommended complementary radiographic study using CBCT in those patients with impacted canines with marked displacement, possible reabsorption of adjacent incisors, or cystic degeneration of the dental follicle. Recently, How Kau et al. [24] proposed a new classification system—the KPG...
index—based on the tridimensional localization of impacted canines provided by CBCT to predict the difficulty of treatment. However, this new classification system needs to be validated by prospective longitudinal studies. A recent systematic review concluded that CBCT is more accurate than conventional radiographs in localizing maxillary-impacted canine [25].

2.1.2. Supernumerary teeth

Supernumerary teeth are usually asymptomatic and are identified during routine radiological evaluation. Radiological study is useful to determine their position. Traditionally, such studies have used periapical, occlusal, and lateral skull radiographs. Periapical radiographs provide a detailed view of the anatomy of the tooth and, through the Clark’s rule [26], can be used to establish the buccolingual and the palatal position of the tooth. However, these
radiographs frequently do not enable a 3D evaluation to be made of the supernumerary tooth with respect to adjacent teeth and neighboring anatomical structures (Figure 4); this information can be important to determine the treatment plan. Liu et al. [27] used CBCT to study 487 patients with a total of 626 supernumerary teeth; in addition, panoramic and lateral skull radiographs had been performed previously in 50 of these patients with supernumerary teeth in the anterior region, allowing comparison of the visualization of the teeth and the adjacent bone structures with the three techniques. CBCT provided visualization qualified as “excellent” in practically all cases (there were only six cases in which visualization of the apices of the incisors was qualified as “reasonable”). CBCT was superior to the panoramic and lateral skull radiographs for all radiological criteria evaluated. Based on these results, the authors recommended that the evaluation of supernumerary teeth should routinely be performed by CBCT, particularly in those cases with multiple supernumerary teeth, malocclusions, or a high intramaxillary position. When extraction of supernumerary teeth is indicated, 3D localization by CBCT can help the surgeon in the choice of surgical access and identification of the tooth to be extracted, reducing trauma to the adjacent soft and hard tissues (Figure 5).

2.2. Periapical disease

Conventional radiographic techniques provide limited information about the origin, size, and situation of periapical lesions [28]. Superposition of adjacent anatomical and dental structures makes it necessary to perform a number of images from different angles [29]. It should be noted that the effective dose of radiation of two periapical radiographs in the area of the molars is of between 0.01 and 0.02 μSv [30], whereas the dose with limited CBCT is between 0.006 and 0.012 μSv [31].

Experimental studies have shown that CBCT is superior to digital or conventional intraoral radiography for the detection of chemically [32] or mechanically [33] induced periapical lesions. Lofthag-Hansen et al. [29] demonstrated the utility of limited CBCT for the detection of periapical pathosis not identified by conventional intraoral radiography. With CBCT, these authors found a larger number of teeth and roots involved and a larger number of lesions extending toward the maxillary sinus than on periapical radiographs. In 70% of the cases studied, the examiners considered that CBCT provided relevant additional diagnostic information in comparison with intraoral radiographs. The authors recommend the use of CBCT when there is a clinical suspicion of periapical disease and no pathology is detected on conventional radiographic techniques, as well as to plan periapical surgery for multi-rooted teeth. On the same subject, Estrela et al. [34] demonstrated that panoramic and periapical radiographs underestimated both the number and size of periapical lesions in comparison with CBCT. Estrela et al. [35] compared CBCT and intraoral radiographs for the diagnosis of periapical pathology in 596 patients with one or more endodontically treated teeth. Periapical pathology was detected in

Figure 5. Supernumerary teeth in the anterior portion of the upper jaw. (a) Cone beam computed tomography (CBCT) reconstruction obtained with I-CAT system (Imaging Sciences International, Hatfield, PA, USA); (b) cross-sectional view of the supernumerary teeth and their relationship with adjacent anatomic structures. Notice a crown erupting in the nasal floor (arrows).
60.9% of cases with CBCT and in 39.5% with intraoral radiographs. Based on these results, the authors proposed a new classification—the periapical index—for periapical pathosis based on the diameter of the lesion and on the expansion or destruction of cortical bone.

CBCT can also be used as a noninvasive diagnostic technique in periapical pathosis. Simon et al. [36] compared the diagnosis of large periapical lesions (granulomas vs. cysts) using CBCT and biopsy. These authors examined 17 lesions with a size equal to or greater than 1 cm × 1 cm, making a preoperative diagnosis based on the density of the lesions measured by CBCT. There was concordance between the preoperative diagnosis based on CBCT and the histological study in 13 of 17 cases. In four of the 17 lesions, the preoperative diagnosis by CBCT was of a cyst whereas the histological result was of chronic periapical granuloma. These results suggest that CBCT could be a rapid diagnostic method without invasive surgery and/or prolonged periods of observation to see if a nonsurgical therapy is effective.

Knowledge of the regional anatomy, such as, for example, root divergence and position in relation to the maxillary sinus or inferior alveolar nerve, and erosion of the vestibular and/or palatine/lingual cortical plate, can determine the surgical approach when planning periapical surgical treatment (Figures 6 and 7). After performing a descriptive study using CBCT to visualize the regional anatomy of the area of the upper first molars, Rigolone et al. [37] suggested the possibility of using a small vestibular access for apicoectomy of the palatal root of the maxillary first molars.

Figure 6. Well-defined radiolucent lesion at the apex of the lower right first molar. (a) Panoramic reconstruction of the CBCT. Two-dimensional measurement of lesion size (blue lines). (b, c) Measurement of the lesion in the axial and coronal sections.
In any case, there appears to be a degree of agreement by authors that CBCT should be reserved for those cases in which conventional radiological techniques are insufficient for providing diagnostic information about periapical pathosis.

2.3. Medication-related osteonecrosis of the jaws (MRONJs)

Medication-related osteonecrosis of the jaw (MRONJ) due to bisphosphonates was described by Marx in 2003 [38] and is characterized by exposure of the bone in the maxillofacial area (which can occur spontaneously or after a dental intervention) occurring in patients treated with antiresortives or antiangiogenics and that does not heal after 8 weeks. The diagnosis of MRONJ is based on clinical and/or radiological findings. The differential diagnosis includes lesions secondary to radiotherapy of the head and neck and malignant diseases of the jaw.

Figure 7. Preoperative evaluation of the lower right quadrant for dental implants treatment. (a) Panoramic radiography. (b) Panoramic reconstruction from cone beam computed tomography (CBCT) obtained with I-CAT system (Imaging Sciences International, Hatfield, PA, USA). Notice a periapical radiolucency in the first upper right molar poorly seen in the panoramic radiography and better identified in the CBCT (arrows). (c-e) Multiplanar reconstruction showing the limits of the periapical lesion (circle) and buccal alveolar plate destruction (arrow). (f) Three-dimensional-rendered model for case illustration.
Radiological evaluation is used to confirm the diagnosis and determine the extent of the lesions. The radiological study must include orthopantomography (OPG) as first-line test, reserving magnetic resonance imaging (MRI), CT, and CBCT for those cases that require complementary tests to resolve the differential diagnosis [39]. A number of radiological signs suggestive of ONJ have been described, including an absence of bone healing and osteosclerosis at the cortical margins of dental sockets after tooth extraction, broadening of the periodontal ligament, osteolysis, altered medullary bone structure with increased density, and the formation of sequestra [40, 41] (Figure 8).

CBCT, as an alternative to CT, has become more widely accepted as a diagnostic technique for 3D imaging in jaw lesions [42, 43]. Although soft-tissue definition can be limited due to a poor contrast resolution, CBCT can provide detailed information about cortical thickness, medullary involvement, irregularities after tooth extraction, and density of the medullary bone; its use has been described in the diagnosis, follow-up, and treatment of patients with

Figure 8. Medication-associated osteonecrosis of the jaws (MROJ). (a) Amplification of the zone of interest in the panoramic reconstruction. (b) Sectional views of the CBCT where the presence of osteolytic lesion is observed with small bone sequestra formation (I-CAT Vision, Imaging Sciences International, Hatfield, PA, USA).
MRONJ [44, 45]. Fullmer et al. [46] described the radiological findings of chronic suppurative osteomyelitis of the mandible on CBCT, including two cases with a history of bisphosphonate use. The authors suggested that the information provided by CBCT was not only of diagnostic utility but also that it was useful for preoperative evaluation of the true extent of the medullary bone involvement, and this information was easily transferred to 3D models that served as topographical references for the surgical treatment.

Fisher et al. [45] and Pautke et al. [41] used CBCT to locate areas of osteolysis and bone sequestra for their subsequent analysis with fluorescent lamps (Wood’s lamp) to direct tetracycline absorption-guided surgical debridement. MRONJ is usually diagnosed in advanced stages, when it starts to become symptomatic [47], and CBCT can therefore facilitate early diagnosis and the identification of sequestra that could be undetectable clinically or on panoramic radiographs. According to these authors, CBCT is a useful screening technique for ONJ in patients on treatment with bisphosphonates and with additional risk factors.

Barragan-Adjemian et al. [48] analyzed 26 cancer patients treated with intravenous bisphosphonates, 18 of them presenting exposure of necrotic bone. CBCT revealed sclerotic and radiolucent bone lesions, and it was possible to measure them. The authors suggested that CBCT examination can be useful for evaluation of the extent of the lesions and for patient follow-up. Treister et al. [49] compared clinical and radiographic features of a series of seven subjects with MRONJ who were evaluated by both CBCT and panoramic radiography. Radiographic findings included sclerosis, cortical irregularity, lucency, mottling, fragmentation/sequestra formation, sinus communication, and persistent sockets. CBCT demonstrated a greater extent and quality of changes compared with panoramic radiography in nearly all cases. Other authors suggested that staging of osteonecrosis of the jaw requires computed tomography for accurate definition of the extent of bony disease [50]. Kämmerer et al. [51] have shown significant advantage of CBCT over panoramic radiography for surgeons with regard to therapeutic planning for MRONJ.

2.4. Oral cancer

The preoperative study of patients with oral cancer usually includes physical examination, blood tests, panendoscopy, and radiological examination. The radiological studies of choice are OPG, CT, and MRI. The technique of choice for visualization of tumor size in the soft tissues and for evaluation of cervical lymph node involvement is MRI, while CT is the technique of choice for evaluation of the presence and extent of bone invasion. The introduction of CBCT represents an alternative for the preoperative study of patients with oral cancer to evaluate the extent of jaw bone invasion.

Closmann and Schmidt [52] described the use of CBCT as a complementary examination for the preoperative evaluation of three patients with malignant lesions of the oral cavity (two squamous cell carcinomas and one osteosarcoma). Examination by CBCT was superior to that of OPG and MRI for evaluation of mandibular invasion and the extent of the lesion in the hard tissues, with the added advantage of lower cost and lower radiation dose than CT. The authors concluded that CBCT could be useful for the preoperative staging of oral cancer and for determining the extent of surgical resection necessary, as well as for planning reconstruction techniques.
In a study of 197 patients diagnosed with oral cancer, Linz et al. [53] have found that CBCT and bone scintigraphy (BS) showed the highest accuracy for the detection of bone invasion and showed better performance than panoramic radiography and CT/MRI. The authors concluded that for the evaluation of bone invasion, CBCT and BS might be the modalities of choice. However, CT and/or MRI remain essential for lymph node staging and for the detection of soft-tissue involvement.

3. Conclusions

The introduction of CBCT represents a great technological advance in the context of oral and maxillofacial radiology as it permits the acquisition of high-quality 3D images and dynamic navigation over an area of interest in real time, with a short scan time and lower dose of radiation than conventional CT. The initial indications of CBCT have been extended by the progressive addition of new ones such as evaluation of the extent of osteonecrotic lesions of the jaw due to bisphosphonates, preoperative staging of oral cancer, and planning reconstructive surgery. As a consequence, this radiological technique represents an interesting complement to conventional radiology in those clinical situations in which 3D imaging can facilitate diagnosis and/or treatment.
