Chapter 7

Temporomandibular Joint Pathology and Its Indication in Clinical Orthodontics

Bakr M. Rabie, Jeremy Ho and Qianfeng Li

Additional information is available at the end of the chapter

http://dx.doi.org/10.5772/intechopen.72651

Abstract

Temporomandibular joint (TMJ) pathology has been an area of study in dentistry specifically a research interest in clinical orthodontics in which treatment option has been a dilemma for practitioners. Discussion between ‘dos’ and ‘don’ts’ in growth modification has drawn spread however opposite opinions from different schools of thoughts in whether growth modification itself is working. To provide a better illustration of biological process within TMJ, this chapter discussed aspects including overall condylar growth; the histological structure of endochondral bone of condyle; extracellular factors that regulate proliferation, differentiation, hypertrophy, terminal maturation and apoptosis of chondrocytes; and molecular regulation of the entire process. An understanding of the pathology, histology, cellular and molecular events related to the morphology and growth of TMJ forms through reading over this chapter; the emphasis of the mechanotransduction mediators and the influence of mechanical strain on the level of expression of genes were presented in details. Novel studies using virus vector stimulating condylar growth through enhancing angiogenesis within a time limit were discussed; also clinical implications in treatment options in relation to mandibular advancement were briefly compared.

Keywords: temporomandibular joint pathology, condylar growth, orthodontics, gene therapy, growth modification

1. Introduction

More than 700 of 6000 known hereditary syndromes involve dental or craniofacial disorders; temporomandibular disorders (TMDs) are one subgroup [1]. TMDs are a class of musculoskeletal disorders related to mouth opening and closing, chewing and other mandibular processes necessitating the involvement of the temporomandibular joint (TMJ) and any of its associated structures [2]. Currently, one of the most widely used diagnostic criteria remains
to be the RDC/TMJ criteria, axis 1 diagnoses by Manfredini et al. which classifies TMJ cases into one of three categories: musculoskeletal issues [3], TMJ disc displacements and joint pain (arthralgia). There are also other classifications of TMDs which focus on inflammation, injury and systemic conditions (Table 1) [3–5].

As TMDs have implications on the quality of life and well-being of affected individuals and their families, it is of major interest to clarify the etiology of TMDs. Several issues have arisen with the understanding of the etiology, treatment options and preventative measures of TMDs. There is a great variability in symptoms of TMDs (ranging from pain and inflammation to limitations of jaw movements) which can even vary in prevalence between genders—as

I. Musculoskeletal issues

A. Myofascial pain: pain or ache in the jaw, temples, face, preauricular area or inside the ear at rest or during function and pain in response to palpation of three muscle sites of the mandible with at least one of the painful sites on the same side as the complaint of pain [3, 4]

B. Myofascial pain with limited opening: myofascial pain with pain-free unassisted mandibular opening 40 mm and maximum assisted opening (passive stretch) 5 mm greater than pain-free unassisted opening [3, 4]

C. Ankylosis: joint stiffness potentially from disease and injury or a consequence of surgery [4, 5] and can be divided into fibrous, fibro-osseous and osseous conditions [4, 5]

II. TMJ disc displacements

A. Disc displacement with reduction: reciprocal clicking in TMJ or clicking in TMJ on both vertical ranges of motion in two of three consecutive trials [3, 4]

B. Disc displacement without reduction with limited opening: history of significant limitation in opening, maximum unassisted opening 35 mm, passive stretch increases opening by 5 mm over maximum unassisted opening, contralateral excursion 7 mm or uncorrected deviation to ipsilateral side on opening and the absence of joint sound or joint sounds not meeting criteria for disc displacement with reduction [3, 4]

C. Disc displacement without reduction, without limited opening: history of limitation of mandibular opening, maximum unassisted opening 35 mm, passive stretch increases opening by 5 mm over maximum unassisted opening, contralateral excursion 7 mm, the presence of joint sounds not meeting criteria for disc displacement with reduction, imaging conducted by either arthrography or magnetic resonance reveals disc displacement without reduction [3, 4]

III. Arthralgia, osteoarthritis and osteoarthrosis

A. Arthralgia: pain in one or both joint sites during palpation; one or more self-reports of pain; for simple cases, coarse crepitus must be absent [3, 4]

B. Osteoarthritis of the TMJ: arthralgia, coarse crepitus in the joint or radiologic signs of arthrosis, classified as a degenerative joint disorder [3–5]

C. Osteoarthrosis of the TMJ: the absence of all signs of arthralgia; coarse crepitus in the joint or radiologic signs of arthrosis; classified as a degenerative joint disorder [3–5]

III. External causes

A. Inflammation: can be acute, chronic or, a third option, infectious, which can be nonspecific or specific to a type of disease [3, 4]

B. Tumors: can be benign or malignant [4, 5]

C. Systemic conditions: include rheumatoid, juvenile and psoriatic arthritis, scleroderma and mixed connective tissue disease [4, 5]

Table 1. General classification of temporomandibular disorders (TMDs).
females have been found to be more susceptible to TMDs compared to males [6]. This has resulted in treatment options being too broad or general, such as cognitive behavior therapy, nonsteroidal anti-inflammatory drugs (NSAIDs) and physiotherapy [6]. While there have been efforts for classification of the etiological factors including a widely known classification by de Boever et al. (Table 2) [7], current literature has shifted its focus to anatomical and histological examination of the structures within the TMJ, to identify contributing factors for TMDs, which will be the focus of this chapter.

2. Anatomy of the TMJ

The temporomandibular joint (TMJ) is an articular disc between the cranium and mandible and, more specifically, centered within the orofacial system, a functional group of structures which includes the masticatory and stomatognathic systems as well as the maxilla-mandibular apparatus (Figure 1) [5, 8]. The TMJ contains the glenoid fossa, TMJ disc (center, anterior and

![Diagram of the TMJ and associated structures](http://dx.doi.org/10.5772/intechopen.72651)
posterior), porous bone and mandibular condyle. It is a synovial joint and is unique in that it is one bone that is composed of two bilateral joints which cannot move independently of each other [6, 9]. Between the two joints is synovial fluid which promotes the hinge and sliding movements of the mandibular condyles required for mouth opening and closing and occlusion of the teeth [6].

The major function of the TMJ includes the coordination of individual tooth positions and other features of the orofacial system [8]. This is accomplished by lateral ligaments which are attached inside of joint capsules, being the structures which stabilize the intra-articular discs [10, 11]. The capsule is surrounded by fibrocartilage (rather than hyaline cartilage) and contrasts in thickness—the anteromedial and medial aspects are thin (0.7 mm), while the lateral and posterior aspects are thick (1.8 mm) [5, 9]. The capsule extends from the glenoid fossa to the neck of the mandible, preventing excessive displacement of the TMJ [5]. The majority of blood supply originates from the trail of superficial temporal, superior articular, anterior tympanic, and pterygoid arteries [5].

2.1. Glenoid fossa

The glenoid fossa is a concave portion of the temporal bone [8]. It borders the articular eminence anteriorly and the tympanic plate posteriorly [5, 9]. The glenoid fossa, similar to the disc and condyle, is a site of angiogenesis when subjected to mechanical stimuli [5, 9]. However, its histological composition has striking differences. Histological examination of the glenoid fossa has recorded fewer posterior layers of chondrocytes than the condyle. As chondrocytes are involved in chondrogenesis in the formation of cartilage to support the growth of the bone by means of endochondral ossification, the glenoid fossa may undergo a reduced level of endochondral ossification and a greater level of intramembranous ossification [5].

2.2. TMJ disc

The disc is fibrocartilaginous and biconcave and takes on a bow-tie morphology [5]. The two ridges of the disc are referred to as bands which attach to different structures. The smaller and shorter anterior band connects with the joint capsule, condylar head and articular eminence [5]. On the other hand, the larger and longer posterior band attaches to the condyle and the temporal bone [9]. The disc attaches to the capsule and neck of the condyle medially. The disc facilitates jaw opening in which the disc moves between the head of the mandible and the articular eminence [5].

2.3. Mandibular condyles

The articular surface of the mandible borders the anterior surface of the mandibular condyles [12]. The mandibular condyles are structures of the human mandible, covered with fibrous tissue composed of predominantly type I collagen, which present a surface for interaction with the articular disc of the temporomandibular joint, composed of avascular fibrous tissue including collagen and fibroblasts [12]. Below this resting, the fibrous layer of the condyles is four layers of cartilage: the proliferative, chondroblast, hypertrophic and erosive layers [12].
Extending further posteriorly than anteriorly, the condyles are convex laterally with a long axis situated medially and partially backwards [13]. The convex lateral extremities of the condyles are connected to small tubercles for attachment to the ligament of the TMJ [13].

Human condyles grow to 15–20 mm laterally and 8–10 mm anteroposteriorly in adulthood [5]. The growth of condyles is attributed to the condylar cartilage which acts as a template for bone growth [12]. The mandibular condyles are unique in that the cartilage (predominantly type II collagen) is known as secondary, compared to main and primary cartilage [12]. Another categorization of the condylar cartilage is articular [14]. However, unlike other types of the articular cartilage such as the synovial or epiphyseal cartilage, it has a striking difference of undergoing adaptive changes in response to external stimuli including mechanical or positional changes (e.g. repositioning of the condyles and/or the mandible, the functioning of the articular discs and the mechanical loading of the condyles) [15–17]. Some of the adaptive changes are related to growth and remodeling such as endochondral ossification and altering or regenerating chondrogenesis [14]. While these changes can occur during or after the natural growth period, there has been study that in adult rats, the remnant condylar cartilage serves more ‘articular’ function than ‘growth’ function as the adult rat condyle stops growth or becomes inactive of endochondral ossification [14]. Additionally, Luder studied adult human condyle structures and found that the cellular layers of organization did not resemble that of growing condyles and attributed the discrepancy to articular remodeling from mechanical loading [18]. As it was determined that articular tissue differed considerably between areas of loading and non-loading, Luder proposed that adult condyles should be divided differently and into three zones of organization—superficial, intermediate and deep [18]. Luder completed a follow-up study and found that features of the articular tissue in the condyles were subject to changes based on age [19]. Most tissue features were altered between 15 and 30 years of age and generally remained stable beyond this age range [19]. During this time, there was a progressive cartilaginification of the newly formed superficial zone, disappearance of the hypertrophic growth plate, appearance of the grid-fibrous fibrocartilage accompanied by a decline in endochondral ossification as well as formation of the subchondral bone plate [19]. From middle age to older age, there was a decrease in cellularity and some senescence and a progressive fibrosis of the intermediate zone. It was determined that the extent of maturation and remodeling and changes experienced in later age were related to articular load bearing [19].

Recently, there has been a spotlight on the mandibular condyles as major contributing factors to TMDs. As active growth sites of the mandible, impaired growth of the condyles has been associated with the development of TMDs [14]. Impairment of condylar development can result in mandibular asymmetry (e.g. hemifacial macrosomia and retrognathia) and problems in mastication, breathing and facial harmony which can lead to the onset of TMDs [14]. As it is evident that the etiological causes of TMDs are multifactorial, an evaluation of the influences and treatment options in the context of condylar growth is of great importance for affected individuals and their respective practitioners. Of major interest in condylar growth is the condylar cartilage for its influence in the growth of the mandible and its adaptive remodeling of the condyles in orthodontic intervention [14]. An understanding of the process of condylar growth and the involvement of cartilage in growth is therefore essential.
3. Steps in mandibular condylar growth

Given the fact that the anatomy of the condyles is clinically relevant in addressing TMDs, it is of importance to distil the major steps and cell types involved in the condylar growth process. There are two major processes involved in the growth of the mandibular condyles: chondrogenesis (cartilage formation) and osteogenesis (bone formation).

Mesenchymal cells eventually undergo one of two processes of osteogenesis by means of endochondral or intramembranous ossification, the latter of which is completed in the absence of the cartilage (Figure 2). In the former process, the mesenchymal cells will first differentiate into prechondrocytes which will mature into terminally hypertrophic chondroblasts [20–22]. This sequence of steps is collectively known as chondrogenesis. The chondroblasts eventually calcify and die, resulting in the bone replacing the cartilage through the invasion of osteoprogenitors which differentiate into osteoblasts [20]. This final step is known as endochondral ossification [23, 24]. Conversely, in intramembranous ossification, mesenchymal cells recruited from neovascularization migrate to the subperiosteal connective tissue and directly differentiate into osteoblasts to give rise to new bone (Table 3) [25].

Figure 2. Schematic of the effects of VEGF during chondrogenesis, neovascularization and osteogenesis.
3.1. Neovascularization

Neovascularization is an essential step in endochondral or intramembranous ossification which occurs in the hypertrophic and erosive layers of the condylar cartilage as well as the glenoid fossa and the TMJ disc [28]. It is quantitatively correlated with endochondral ossification and is an indicator of osteogenesis in the replacement of dying cartilage with new bone [20]. Neovascularization functions by replenishing the population of mesenchymal cells for osteogenesis as blood vessels are the regions where progenitor cells are able to diffuse out and into the surrounding tissues [28].

While neovascularization has been determined to play a major role in condylar bone formation, it is of future interest to investigate the glenoid fossa and the TMJ disc, regions also characterized by mesenchymal cells and chondrocytes [5], as additional potential regions of neovascularization and subsequent bone growth. However, irrespective of anatomical location, an understanding of the factors influencing each of the steps in bone growth in the condyles and its associated regions is of major relevance for improving the management of TMDs.
4. Factors influencing condylar growth

Factors influencing the growth of condylar cartilage can be categorized into cellular (Table 4) and molecular factors (Table 5).

4.1. Factors at the cellular level

Cellular factors can be defined as factors that exert their activity at the extracellular level, including growth factors, cytokines, extracellular matrix (ECM) and other types of proteins. Growth factors and cytokines serve as local mediators in response to mechanical and inflammatory stimuli, while ECM serve as intercellular structural support [14].

I. Growth factors

A. Insulin-like growth factor (IGF): found in chondrocytes [35, 36], mediates growth and development of the cartilage and bone [14, 37]  
B. Fibroblast growth factor (FGF): found in proliferating and chondroblast layers [14, 36]; regulates skeletal development and postnatal osteogenesis (e.g. FGF-2 promotes angiogenesis, inhibits the terminal differentiation of chondrocytes and reduces the formation of the bone) [14]  
C. Vascular endothelial growth factor (VEGF): refers to 4.1.1  
D. Connective tissue growth factor (CTGF): found in hypertrophic layer [38], regulates cartilage ECM and VEGF-A expression [38]. CTGF null or deficiency impairs endochondral ossification [39]

II. Cytokines

A. TGF-β: found in site of endochondral ossification, articular cartilage and growth plate [40, 41]; stimulatory and inhibitory roles dependent on concentration, culture period and state of cellular differentiation [42–44]; generally inhibits chondrocyte maturation and hypertrophy and alkaline phosphatase activity [45–47]  
B. Bone morphogenetic protein (BMP): BMP-2 and BMP-4 are involved with cellular proliferation by regulating endochondral ossification [48]; activity of BMP-2 can be inhibited by Wnt signaling [14]

III. Extracellular matrix

A. Type II collagen: supports cartilage formation [12]  
B. Type III collagen: regulates bone repair and development [49]; cross links are weaker than type I collagen and therefore can support replacement by type I collagen in remodeling [28]  
C. Type X collagen: short-chain collagen [20]; correlated to the hypertrophic phenotype and marks the transition to osteogenesis [20]

IV. Other proteins

A. Parathyroid hormone-related protein (PTHrP): refers to 4.1.2  
B. Indian hedgehog (Ihh): refers to 4.1.3  
C. Matrix metalloproteinases (MMP-1, MMP-9): found in hypertrophic layer [50]; mediates the transition to osteogenesis, angiogenesis and further proliferation of the hypertrophic chondrocytes [20, 50]; facilitates remodeling of the bone by degrading matrix [51]

Table 4. Analysis of the cellular factors involved in condylar growth and, if applicable, the localizations of its respective activities.
4.1.1. Vascular endothelial growth factor (VEGF)

VEGF is one of the most prominent regulators of mandibular condylar growth. It is found mainly in the hypertrophic layer of the condylar cartilage [24, 28, 52, 53], but traces have been discovered in the proliferative layer [54]. VEGF serves multiple functions in supporting the growth of the condyles including the coordination of the death of chondrocytes, function of chondroblasts, remodeling of ECM, secretion of growth factors and cytokines, angiogenesis as well as formation of the bone [12, 25, 26, 55].

Observing each of the functions of VEGF in greater detail, the coordination of chondrocyte death is accomplished by guiding of mesenchymal cell differentiation towards osteogenesis by bringing the cells to the mineralization front for calcification [24, 56, 57]. Additionally, VEGF-A has been the main isoform which facilitates the progression of angiogenesis [12]. VEGF in general supports rapid vascularization essential to healing and induction of bone associated with bone matrix that has been demineralized [58]. With respect to supporting bone formation, VEGF has been noted to increase mandibular length, and its expression has been correlated with the quantity of newly formed bone in the posterior of the condyle [12]. It is therefore evident that VEGF is a major therapeutic target of interest in research towards regulation of condylar growth.
4.1.2. Parathyroid hormone-related protein (PTHrP)

Another major regulator of condylar growth, PTHrP, is found in the transition zone between the proliferative and hypertrophic layers [59, 60]. It controls the condylar bone formation by facilitating and mediating the biomolecular pathway through which chondrogenic phenotype is shifted to osteogenesis [20]. This is accomplished by slowing down the hypertrophy of mature chondrocytes to promote further maturation and to provide more time to develop the cartilage in preparation for osteogenesis [33, 61]. By promoting further maturation and delaying the transition from chondrogenesis to osteogenesis, the population of chondrocytes continues to rise, leading to an increase in cartilage volume and subsequently bone formation. Additionally, PTHrP induces the differentiation of mesenchymal cells through SOX-9, a transcription factor which serves to positively regulate the growth of the condyles [33].

4.1.3. Indian hedgehog (Ihh)

Compared to other factors at the cellular level, Ihh functions as a highly dynamic mechano-transduction factor which increases in expression in response to mechanical stimuli [12]. It is expressed by prechondroblasts and early hypertrophic chondrocytes in the proliferative layer [12, 62]. Ihh has a variety of effects on the TMJ and condyles including supporting early development [63] by regulating mesenchymal cell and chondrocyte proliferation and cartilage development (most notably type II collagen) in chondrogenesis as well as the transition to osteogenesis under mechanical strain [34, 64-66]. Interestingly, Ihh can also function as a molecular factor by shortening the turnover and enhancing the renewal of condylar cells [34] by upregulating cyclin D1, the ‘gatekeeper’ of the transition from the G1 to the S phases of the cell cycle [65, 67].

4.1.4. PTHrP/Ihh negative feedback loop

Rabie et al. postulated that PTHrP and Ihh activities are linked through a negative feedback loop which regulates the development of the growth plate [5]. In the feedback loop, when PTHrP production is fleeting and not sufficiently stimulating chondrocytes, chondrocytes stop proliferating and maturing [66]. The chondrocytes begin to synthesize Ihh in the hypertrophic layer which acts on the chondrocytes by means of receptor-mediated signaling [66]. Ihh increases the proliferative rate of the chondrocytes and stimulates the production of PTHrP at the terminus of the bone. PTHrP then maintains the chondrocytes in a proliferative state and delays further maturation and differentiation which delays Ihh production [34]. As a result, the PTHrP/Ihh negative feedback loop modulates the pace of proliferation and differentiation of the chondrocytes to regulate cartilage and eventual bone formation [12].

4.2. Factors at the molecular level

Molecular factors can be defined as factors that operate within the cell by means of genetic and other intracellular factors. Such factors can be categorized into transcription factors, novel genes specific for condylar growth and other intracellular proteins. Transcription factors control genetic expression, while intracellular proteins control signal transduction and cell cycling pathways.
4.2.1. SOX-9

Targeted in PTHrP signaling, SOX-9 is a transcription factor that regulates the differentiation process from mesenchymal cells to hypertrophic chondrocytes [12]. Additionally, SOX-9 prevents premature differentiation and regulates type II collagen synthesis and cartilage formation through activation of the enhancer region of Col1a2 and Col2a1 [20, 75–77]. It is able to accomplish its activities by recognizing the DNA sequence of CCTTGAG and other members of the high mobility group (HMG) box class of DNA-binding proteins [71].

To understand how SOX-9 facilitates differentiation, it is vital to recognize that SOX-9 is expressed in mesenchymal cells, prechondroblasts and early differentiated chondrocytes but not in hypertrophic chondrocytes [78]. In mesenchymal cells, SOX-9 is required for differentiation into prechondroblasts. Later in the prechondroblast stage, SOX-9 supports the proliferation and further differentiation into early and proliferating chondrocytes. At the same time, SOX-9 regulates the expression of Noggin, an anti-apoptotic gene to support the proliferation of the chondrocytes [71]. After this stage, SOX-9 inhibits the transition from proliferative to hypertrophic chondrocytes to control subsequent endochondral ossification. Overall, SOX-9 is involved in cell proliferation of successive cell types in the earlier stages of chondrogenesis, but it also serves to prevent the hypertrophy of chondrocytes (Figure 3).

5. Interventions to address condylar growth

Given the working understanding of the stages and factors involved in condylar growth, researchers have found the condyles to be clinically relevant to the development and morphology of the orofacial complex [14, 20]. The condyles have been studied as a therapeutic target in addressing TMD and craniofacial issues in general. Two leading interventions to reactivate and control condylar growth have been the use of the recombinant adeno-associated virus (rAAV) vector and the application of mandibular advancement orthodontic appliances.

5.1. Intervention by the rAAV vector

The rAAV vector has become of interest in in vivo TMD therapy as it has been shown to overcome many limitations involved in the gene therapy of the cartilage and bone [79, 80]. Some advantages of the vector include reduced pathogenicity and immunogenicity, which supports long-term expression of transgenes which can be restricted to defined anatomical locations including specific oral tissues and success in transfecting many types of dividing and nondividing cells due to its size of 22–25 nm [55, 79, 81]. At this small size, rAAV-VEGF has been demonstrated as a suitable in vivo vector to significantly induce condylar growth by diffusing through the layers of the cell surface and infect with regular and hypertrophic chondrocytes to promote VEGF-mediated growth [79]. The systemic safety of the rAAV-VEGF vector has also been studied as exogenous VEGF was not identified in reverse-transcribed RNA samples of remote organs (e.g. heart, spleen and kidney) of transfected subjects [79].
Rabie et al. investigated the effect of in vivo rAAV-mediated VEGF administration on female Sprague–Dawley rats and found increases of the length of the condylar process axis (B-F) and the mandibular length from day 30 post-surgery and beyond [55]. The condylar width and length also increased during the same time period [55]. The growth of the condyle was upwards and backwards such that the greatest cellular response was found in the posterior condyle compared to the anterior surface [55]. This supported the adaptability of the condyle in directional changes in the growth of the mandible [24]. In addition, other studies have found a gain of function of VEGF, or VEGF gene has been associated with increases in neovascularization and regeneration of the bone in defective condyles [82, 83]. This has also reinforced the significance of rAAV-mediated VEGF as an appropriate option in contributing to neovascularization and endochondral ossification [28].

Figure 3. The roles of SOX-9 in each successive step of chondrogenesis towards endochondral ossification in the condyles. SOX-9 functions to commit mesenchymal cells to differentiate into prechondroblasts and supports the transition of prechondroblasts to early and proliferating chondrocytes but inhibits hypertrophy of the chondrocytes prior to the calcification of the cartilage.
Most notably, it was determined that there was a delay in morphological effects of rAAV vector such that VEGF levels were increased on day 14 while chondrogenesis and osteogenesis occurred on days 21 and 30, respectively [55]. This finding had clinical implications in terms of understanding that gene therapy required a careful balance of inhibition or reinjection of the viral vector to address the potential consequences of overgrowth or relapse [55].

5.2. Intervention by mandibular advancement orthodontic devices

Recently, it has been proposed that condylar growth can be induced by forward mandibular advancement which has been noted to mirror natural growth [21]. Animal studies of mandibular advancement treatment on rats have reported the enhancement of chondrocyte maturation and endochondral ossification which give rise to new bone and condylar growth [84].

Three major factors of consideration include the age of the patient, the length of the treatment and stepwise versus single-step mandibular advancement. First, there have been recommendations of using functional appliances during or after the peak pubertal period to observe the greatest stability of treatment results [85–87]. Second, recommendations have been made to extend the commonly studied period of mandibular advancement of 6 months to 1 year in order to support the maturity of type I collagen [88–90]. Two other separate studies also noted that the treatment length was correlated to the maintenance of the effects of the orthodontic intervention [91, 92]. However, there have been mixed conclusions on the effect of lengthening the treatment period. Hagg et al. and Phan et al. found opposing trends of the length of treatment on the maxilla and the mandible, increasing the effect for the former and decreasing the effect for the latter [93, 94].

5.2.1. Stepwise versus single-step mandibular advancement

There has been extensive literature for the comparison of two approaches of mandibular advancement: stepwise versus single-step advancement. Currently, stepwise advancement has been determined as being the preferable therapy.

One of the reasons supporting stepwise advancement is the improvement in skeletal effect, most notably the sagittal jaw relationship with the maxilla, assuming a more forward positioned mandible due to more growth than single-step advancement [21, 95]. This improvement may be attributed to work completed by Petrovic et al. who found that the forward repositioning of the mandible periodically increases the rate and amount of growth in the condylar cartilage [96]. Van Lam and Rabie also found that stepwise treatment was correlated with significantly greater new bone formation [21].

From a cellular and molecular perspective, stepwise advancement that exceeded a minimum threshold of mechanical strain resulted in increases in Ihh, type II collagen, PTHrP and VEGF [34, 57, 97–100]. Thus, stepwise treatment involves repeated cycles of mechanical strain and increases neovascularization which results in increases in eventual new condylar bone formation [57]. Studies have shown that manipulating the amplitude of mechanical strain by stepwise advancement can significantly impact VEGF production by chondrocytes [55]. Moreover, the later stages of stepwise treatment are responsible for more VEGF production...
and subsequent condylar bone formation [57]. The extent of condylar growth modification from mandibular advancement has been determined through changes in measurements of the condyle and documented effects at the cellular and molecular levels (Table 6).

One modality of stepwise advancement in orthodontic treatment is the Herbst appliance; due to the advantages of stepwise treatment, it has been recommended to be included in an

Table 6. Analysis of the factors affected by means of orthodontic mandibular advancement.
orthodontist’s armamentarium [72]. The Herbst appliance has been evaluated with young adult patients and has yielded promising results in the treatment of Class II malocclusion [12]. It has been identified to operate by reactivating prechondroblast activity [12]. However, Pancherz has found several limitations of the Herbst appliance. The appliance has been met with concerns of relapse in cephalometric angle measurements after treatment [88, 90]. Additionally, it is most effective with Class II cases and thus cannot be used by individuals who have fully completed growth [90]. Thus, Pancherz has recommended the use of removable functional appliances post-treatment to maintain the effects from the Herbst appliance [90].

6. Conclusion

There have been considerable efforts to elucidate the etiological factors of TMDs and understand the factors regulating the growth of the TMJ and mandibular condyles at both the cellular and molecular levels. Current approaches to stimulating and controlling the growth of the condyles to address craniofacial abnormalities and/or TMDs have proven to be promising. Further research will be required to develop orthodontic treatment modalities that can be applied in a clinical setting on a case-to-case basis.
