Application of Medical Imaging in Diagnosis and Assessment of Myocarditis and Pericarditis

Yousif Mohamed Y. Abdallah and Nouf Abdhadi

Abstract

Medical imaging is one of the most essential means in the investigation of cardiac disorders. In patients, the detection of the whole heart and its adjacent tissues is a crucial procedure since it helps in myocarditis and pericarditis management. Weekly, there are millions of cardiac imaging performed globally. Medical imaging and processing techniques such as image segmentation, augmentation, and scrutiny can detect cardiac lesions rapidly and precisely. This chapter discusses the application of medical imaging in the diagnosis of myocarditis and pericarditis. This chapter also summarized how to demonstrate image interpretation challenges using diverse image processing procedures and techniques.

Keywords: medical imaging, diagnosis, myocarditis, pericarditis

1. Introduction

The pericardium is a muscular sac that covers the heart and cases its major blood vessels. It facilitates and greases the heart motions [1–3]. In embryonic stage, the internal layer of the pericardium forms the myocardium prior fused with the exterior layer of the fibrous layer [4–7]. Those layers are a few millimeters thick and they are separated from each other. The pericardium gets the blood from inner mammary arteries and its inversion from the phrenic nerve [8, 9]. The pericardium separates from the sternum, vertebral bodies, and diaphragm through many ligaments (Figure 1) [10].

The symptoms of myocarditis are common especially in middle-aged patients [11]. Those diseases can cause discomfort, chest pain, tiredness, breathlessness, and repeated visits to clinics. The coronary vessel disease is one of the causes of myocarditis and pericarditis [12–14]. The virus infection is the main cause of myocarditis. This infection is usually associated with serve viral infection. This infection may cause the injury to the myocardium tissues, and it is associated with the accumulation of fluid and local death of tissue, contingent on its nature and extent [15–18]. Fungal infections are infrequent and include aspergillosis, blastomycosis, and candidiasis. The tissue can be recovered within days. In acute cases, complete functional tissues work within weeks [19]. Cardiomyopathy may cause the consequences of the chronic inflammatory process (Figure 2) [20, 21].

The causes of occurrence of acute myocarditis are idiopathic. Pericarditis is an inflammatory process that affects the pericardium tissues. The signs of pericarditis
are rub, abnormal ECG findings and possible pericardial effusion, chest discomfort, and breathing difficulties. The pericardial rub is best heard at the end of the expiration phase with patient sloping frontward [22–24]. About 30% of patients with myocarditis might be accompanied with pericarditis. Pericarditis is difficult to detect. Some postmortem studies suggest that pericarditis is a subclinical type. Pericarditis accounts for 5% of patients who are attending to emergency rooms due to myocardial infarction and chest discomfort [25–29]. On laboratory results, pericarditis can be detected in a troponin I test. Nevertheless, the elevation of troponin (I) is not used as the adverse prognosis of the disease [30, 31]. Serology may approve the cause as infectious or autoimmune pericarditis. Acute pericarditis onsets with mild signs and symptoms and its treatment lasts for 6 weeks. The infection symptoms might reoccur within 4–6 weeks [32, 33]. The prevalence of pericarditis may include idiopathic, tuberculosis, viral (HIV infection) or systemic infection, cancer (breast, leukemia, lymphoma, and lung), radiation therapy (about 4% of mediastinal Hodgkin’s disease), cardiac surgery (20% of the cases

of bypass graft surgery), and percutaneous heart examinations [34–36]. The bacterium spreads to the pericardium by blood or direct extension of the adjacent organs. Incidence of myocarditis has been stated after smallpox immunization. The neoplastic pericardium is a secondary cause of the pericarditis [37]. Patients with acute pericarditis have progressive disease and discomfort. This discomfort gets worse when the patient is lying supine. The pain in the area refers to the trapezius muscles and phrenic nerve. Fever might accompany the viral pericarditis [38–40]. Electrocardiogram (ECG) is the most frequent tool for acute pericarditis study. It shows a saddle shape that reflects subepicardium infection. In ECG graph, acute pericarditis shows no Q-wave and loss of R-wave. Imaging of the cardiac tissue has a limited role especially in uncomplicated acute pericarditis. Chest radiographs show the cardiomegaly and pericardial effusion (250 mL). Ultrasound imaging (M-mode and Doppler) is used to differentiate constrictive and restrictive cardiomyopathy. In the pediatric, a transesophageal probe is used to detect diastolic dysfunction. Cytological examinations of pericarditis include glucose, protein, cell count, bacteria and virus culture, and gram and Ziehl-Neelsen stain test. Myolemma and sarcolemma can detect immune-mediated pericarditis. In neoplastic conditions, the high level of the carcinoembryonic antigen is detected. Pericardial biopsy is performed in the granulomatous or malignant suspicion [41–43].

2. Clinical presentation of myocarditis and pericarditis

The medical signs of acute pericarditis and myocarditis include malaise, rash, tiredness, arthralgias, and respiratory and digestive syndromes. The acute infection continues for few weeks. Patients might attend the clinic with chest discomfort, breathlessness, tiredness, and syncope. Cardiac beat disorders are common and include both atrial and ventricular with the possibility of atrioventricular blockage. The European study of the inflammatory disease showed that 72% had dyspnea and 32% chest discomfort. The medical signs in pediatric patients differ according to their age. Kids may have anxiety, tiredness, raised temperature, loss of appetite, increased breath rate, increased heartbeats, and blue skin due to lack of oxygen. Symptoms in toddlers might comprise of chest and abdominal discomfort, muscle pain, tiredness, cough, and fluid accumulation in tissues. The degree of symptoms is reliant on the age of the kid. Toddlers often have and might require progressive cardiovascular and respiratory care in the initial phases of their disease than adults [44].

3. Medical imaging in diagnosis and assessment of myocarditis and pericarditis

3.1 Electrocardiography

Echocardiography is beneficial for assessing cardiac tissue dimensions, wall width, systolic and diastolic, and intracavitary thrombi. This technique can assess cardiac failure. Myocarditis has no special radiographic features in this technique. Nevertheless, myocarditis is characterized by widened, enlarged, and ischemic cardiomyopathies. This technique is commonly used as a diagnostic tool. The accuracy of electrocardiography for pericarditis and myocarditis is about 47% because ECG findings are basic T-wave deviations (Figure 3) [45].

The classical ECG examination is comprised of four stages of changes and it is described in about 50% of cases.
Those stages are:
- **Stage 1**: (hours to a few days): the ST elevation and depression of the PR segment.
- **Stage 2**: (first week): control of the ST and PR segments.
- **Stage 3**: T-wave inversions.
- **Stage 4**: standardization of ECG [46, 47].

### 3.2 Chest X-ray

Chest radiograph is a radiographic procedure that uses low-energy ionizing radiation (X-rays) to visualize the chest organs. This procedure is very crucial in the assessment of lung and heart signs and symptoms such as cough, chest infection, injury, and discomfort [48]. This procedure is used to evaluate and screen heart inflammatory diseases such as myocarditis and pericarditis. This procedure is noninvasive and does not require special patient preparation. Chest radiography is a standard procedure for myocarditis and pericarditis patients. A distended cardiac shadow might be identified with accumulated fluids. Chest X-ray shows cardiac enlargement as a result of chamber dilatation, pericardial effusion, interstitial infiltrates, and pleural effusions (Figure 4) [49–51].

![Figure 4. Shows chest radiograph of myocarditis patient.](image)
3.3 Computed tomography (CT)

Computed tomography provides clear images of pericardium space and infection complications. Nuclear cardiology can delimit the pericarditis. Pericardiocentesis is indicated for pericardial effusion, pus-filled pericarditis, and suspected tumor (Figure 5) [52].

3.4 Nuclear medicine

FDG PET-CT can be used for visualization of myocarditis and pericarditis. This technique helps to differentiate between the acute and chronic cardiomyopathy diseases. Recently PET/MRI is used for detecting myocarditis and pericarditis [53]. The evaluation of myocarditis using nuclear scanning had started in the early 1970s. This scanning technique had started by using gallium-67 to visualize the internal...
muscles of the heart. In the early 1980s, the utilization of SPECT enhanced the results of detection of the myocardial tissues. So the detection of the myocarditis and pericarditis became easier than using planar scanner. The radioiodine-labeled (I-111) was introduced in the 1970s. This radioactive test was used to detect monoclonal antimyosin antibodies because of its ability to detect the necrotic area (Figure 6) [54].

4. Using cardiovascular magnetic resonance (CMR) in the assessment of myocarditis and pericarditis

Recently, CMR has become a crucial tool for acute myocardial tissue damage. In Europe, CMR represents the differential diagnosis of 1/3 of the cardiac cases [55]. CMR is used to detect the features of myocarditis edema and is related with pericardial fluids, which might be visualized together in images. CMR enables the evaluation of myocardial fluid accumulation and infection process. The CMR gives high accuracy and recognition of the acute inflammatory process, regardless of image quality differences due to the scanner and applied procedure [56, 57]. CMR might detect the accumulation of fluids which represents [58]. The body coil might help in the reduction of acquiesced signal noise, signal scattering, flow suppression, suitable slice width, and sufficient scanning time. Sixteen short-axis views are suggested to decrease the artifacts associated with the sluggish transplanar blood stream. In females, the mild edema is scanned using the signal that normalizes to skeletal muscle in similar slice. The gadolinium (Gd) might increase the recognition of the myocarditis edema especially after using contrast media-sensitive sequence and T1-weighted image. The comparison between the signals, prior and throughout the contrast-enhanced scanning, might show the large volume of edema. Consequently, using the adjacent muscle as reference helps in detecting of the edema area [61–63]. Recently, many studies showed that using Lake Louise criteria does not affect the diagnosis, but they increase the possibilities of the false-positive probability rate (Figure 7) [59].

Other studies showed that an amplified Gd enhancement ratio of more than 4.0 is related to patient complications and disease prognosis [60]. T2-weighted images might be used to detect myocardial edema, which indicates the presence of myocarditis. This technique had shown high precision and accuracy. The patients’
movements and image artifacts affect the quality of the images. The new scanning protocol overcomes those problems by using the short acquisition time [61–63].

5. Conclusion

Myocardium inflammation is considered as a serious condition that affects both pediatric and adult patients with fetal consequences disease. The chronic myocardial inflammation might eventually lead to cardiac failure. Recently, the evolution in tools of diagnosis, screening, and treatment might decrease the morbidity rate of myocarditis and pericarditis.

About 10% of myocarditis has been discovered in autopsy. Many studies had shown that the best modality to diagnose the myocarditis is a biopsy. Many imaging techniques might be used to diagnose myocarditis and pericarditis; nevertheless, the CMR is the most crucial and precise analytical modality. CMR might help in differentiating between the myocardial infraction, inflammation, and injuries and the degree of severity. The fluoroscopic endomyocardial procedures have low complications compared with other invasive tools. The advance CMR protocols are used to improve the diagnosis and reduce the morbidity.
