Chapter

Histopathology and Molecular Pathology of Vitiligo

Amit Kumar Yadav

Abstract

Vitiligo is a common skin disorder that manifests as whitish macules. There is no special geographic or sex predilection. Vitiligo is a multifactorial disorder. The various theories proposed include neutral theory, autoimmune theory, zinc-α2-glycoprotein theory, viral infection, intrinsic theory and melanocytorrhagy theory. However, the currently favored opinion is that there is a convergence of various theories known as the convergence theory. The basic defect is the absence of functional melanocytes from the epidermal melanin unit. This absence can be demonstrated by using special stains like Fontana-Masson, immunohistochemistry like HMB-45 and Melan-A and electron microscopy. Margins of lesions especially early lesions show inflammatory cells principally CD4+ and CD8+ T cells. The cornerstone of management in vitiligo is correct categorization of a case into stable and unstable vitiligo. This distinction is based mainly on clinical criteria. It is recommended that while evaluating biopsies, histopathological examination should be primarily concentrated on evaluating five histopathological variables—spongiosis, epidermal lymphocytes, basal cell vacuolation, dermal lymphocytes and melanophages. These parameters are then scored using a scoring system, and the recommended diagnoses based on these scores are given. Adoption of a systematic reporting system brings more consistency and objectivity in the diagnosis.

Keywords: vitiligo, multifactorial, convergence theory, melanocytes, histological scoring

1. Introduction

Vitiligo is a common acquired, idiopathic, progressive disorder which is characterized by the development of depigmented milky white macules of variable sizes. These often enlarge and coalesce to form extensive areas of leukoderma [1–3]. It equally affects both sexes with a worldwide prevalence of 0.1–2% [4]. It is a psychologically devastating and frequently resistant to treatment [5, 6]. The basic defect in vitiligo is a selective destruction of functional melanocytes [7].

The role of histopathology in the diagnosis of vitiligo is not yet fully established. So much so that routinely in these cases biopsy is not performed. The diagnosis is made primarily on clinical grounds.
2. Pathogenesis

Vitiligo is a multifactorial disorder [8, 9]. In its genesis both genetic and non-genetic factors are believed to play a role. It is observed that clinically no two patients of vitiligo are alike. This suggests that etiology also varies among different patients. Due to the observed variation in clinical manifestations of the disease, it seems likely that etiology of vitiligo may differ among patients [10]. These several theories have been combined into the convergence theory [11] which is currently the most accepted theory.

Briefly in the earliest theory, it was proposed by Lerner that vitiligo was neural in origin [12]. This theory could explain the segmental form of vitiligo which follows dermatomal distribution and is associated with hyperhidrosis and emotional disturbances. In another study the role of sympathetic nervous system in vitiligo was studied [13]. It was observed that the cutaneous blood flow in the lesional skin was three times higher than the normal skin in cases of segmental vitiligo. However, in other cases of non-segmental vitiligo, this was not observed.

Studies on the expression of neural proteins like neuropeptide Y (NPY), calcitonin gene-related peptide (CGRP), vasoactive intestinal polypeptide (VIP) and polyclonal general neuronal marker (PGP) have shown variable results. In one study NPY expression was found to be increased in cases of segmental vitiligo [14]. It is proposed that precipitating factors like stress lead to increased NPY expression [15].

But this theory failed to explain the other forms of vitiligo. For that matter generalized or non-segmental vitiligo is better explained by autoimmune hypothesis. In previously done studies, antibodies against various targets like tyrosine hydroxylase, melanin-concentrating hormone receptor-1 (MCHR1), tyrosinase [16] and pigment cell surface antigens [17] have been demonstrated. In a study carried out to evaluate the various immunoglobulins, it was observed that 80% of active vitiligo patients showed the presence of IgG and IgM against melanocytes [17]. Other studies have shown the presence of anti-thyroglobulin antibodies, antithyroid antibodies, anti-thyroperoxidase and anti-smooth muscle antibody in these cases [18, 19].

Besides humoral immunity, cell-mediated immunity may also play an important role. Immunohistochemical examination of perilesional skin in vitiligo patients showed increased CD8:CD4 ratio and HLA-DR production along suprabasal and basal keratinocytes. Macrophages were found to be quite numerous [20]. However, not only the immune cells and antibodies but expression of various cytokines is also increased. Chief among these which have been studied are tumor necrosis factor-α (TNF-α), interferon-γ (IFN-γ) and IL-10 [21, 22]. IL-17 has also been shown to be significantly increased in cases of vitiligo [23].

The redox (reduction–oxidation) state of vitiliginous patients has been studied by many authors. These studies have shown increased serum levels of selenium, superoxide dismutase (SOD) and malondialdehyde (MDA) [24, 25]. Increased levels of these substances indicate the presence of oxidative stress in vitiligo. Increased levels of tetrahydrobiopterin [26] and xanthine oxidase [27] leading to increased levels of H₂O₂ may also be contributory.

Few authors have pointed towards the role of zinc-α₂-glycoprotein (ZAG) in the pathogenesis of vitiligo. They hypothesize that lack of ZAG causes impaired melanocytic adhesion to other cells in the epidermis [28, 29]. The efficacy of zinc in the treatment of vitiligo may be due to its ability to precipitate ZAG at the site of vitiligo [30].

The role of viral infection in vitiligo has been proposed by certain authors. The potential candidates include hepatitis C virus (HCV) [31], cytomegalovirus (CMV) [32], Epstein–Barr virus (EBV), hepatitis e virus, herpes virus and HIV [33]. However, the evidence available is scant and not conclusive enough to attribute a significant role for viral agents in vitiligo.
The intrinsic theory states that in vitiligo there is loss of melanocytes due to various abnormalities which lead to increased apoptosis [34] and accelerated cell senescence [35, 36]. Studies done previously have shown various abnormalities in the melanocytes including cytoplasmic vacuolization, DNA marginalization, dendrite loss and detachment [36, 37]. The evidence in favor of increased apoptosis in vitiligo includes reduced expression levels of the antiapoptotic proteins Bcl-2 and FLIP in vitiliginous skin as compared to normal skin [34]. On the other hand, marked increase in the expression of proapoptotic factors such as Bax and p53 along with the various caspases has also been observed [34].

The melanocytorrhagy theory states that in vitiligo there is chronic melanocyte detachment and loss caused by trauma and other stressors which include catecholamines, free radicals or autoimmune elements [38].

However, the consensus opinion of majority of experts is that vitiligo occurs due to convergence of these various pathways [39]. These are also depicted in (Figure 1). The author also is in agreement with this view; however, it is likely that in various subtypes of vitiligo the relative contribution of these pathways may vary. For example, in segmental vitiligo the neural theory may be more relevant than the other theories, whereas the same may not hold true for vitiligo vulgaris.

3. Histopathology

In order to understand the histopathology of vitiligo, it is essential to first understand the concept of epidermal melanin unit [40]. Melanocytes are neural crest derivatives, and they reach their final destination of basal layer of the epidermis and hair follicles via a process of migration. Each melanocyte then transfers its melanosomes to approximately 36 keratinocytes via a unique mechanism known as the shedding vesicle system. In the normal skin in the basal layer of the epidermis for every five basal keratinocytes, there is a presence of a single melanocyte [41].

The basic histopathological finding in vitiligo is the absence of functional melanocytes in the basal layer of the epidermis (Figure 2) [42–44]. This absence can also be demonstrated by using special stains like Fontana-Masson (Figure 3) [45].
Immunohistochemistry for melanocyte-specific markers like HMB-45 and Melan-A and electron microscopy can also be performed for this purpose.

Other changes that have been observed include degenerative changes in the nerves and adnexa like sebaceous glands and hair follicles especially in long-standing cases [46].

In the margins of lesions especially early lesions, often inflammatory cells are seen. Principally, these cells comprise of CD4+ and CD8+ T cells [47]. These cells have been shown to demonstrate melanocyte-specific cytotoxicity [48]. At the margins of the lesions, melanocytes have been observed to show morphological changes like cellular enlargement, cytoplasmic vacuolization and long dendritic processes [29].

However, usually skin biopsy is not performed for making the diagnosis as it is primarily a clinical diagnosis. The cornerstone of its management is correct categorization of a case into its two broad types—stable and unstable vitiligo. This distinction is at present based mainly on clinical criteria because the histopathological
features are not fully established. In a study carried out by the author, a reliable and systematic approach towards this diagnostic challenge has come up [49]. In that study the biopsies (3-mm punch) were taken from the margin of the active lesion.

The author recommends that while evaluating biopsies from cases of vitiligo histopathological examination should be primarily focused on evaluating five histopathological variables—spongiosis, epidermal lymphocytes, basal cell vacuolation, dermal lymphocytes and melanophages (Figure 4). The morphological criteria used to assess these parameters are listed in Table 1. All the cases are then scored

4. Conclusions

Vitiligo is a common skin disorder which is characterized by the presence of depigmented milky white macules of variable sizes. Although there are various theories on its etiopathogenesis, the consensus opinion is that vitiligo occurs due to convergence various pathways. The basic histopathological finding in vitiligo is the absence of functional melanocytes in the basal layer of the epidermis. However, in order to evaluate for stability, the histopathological examination should be primarily focused on evaluating spongiosis, epidermal lymphocytes, basal cell
vacuolation, dermal lymphocytes and melanophages. It is recommended to score these parameters, and the final report should incorporate recommended diagnosis based on the score. This will bring more objectivity and consistency in reporting these biopsies.
