Porcine Islet Cell Xenotransplantation

Rajeswar Chinnuswami, Abid Hussain, Gopalakrishnan Loganathan, Siddharth Narayanan, Gene D. Porter and Appakalai N. Balamurugan

Abstract

This article reviews the rationale, sources and preparation of pig islets for xenotransplantation. Pancreatic islet cell transplantation is an attractive alternative and an effective treatment option for type 1 diabetes, however, donor pancreas shortages prevent islet transplantation from being a widespread solution as the supply cannot possibly equal the demand. Porcine islet xenotransplantation has the potential to address these shortages, and recent preclinical and clinical trials show promising scientific support. Pig islets provide a readily available source for islet transplantation, with the recent trials in non-human primates (NHPs) demonstrating their potential to reverse diabetes. The risk of zoonosis can be reduced by designated pathogen-free breeding of the donor pigs, but porcine endogenous retroviruses (PERVs) which are integrated into the genome of all pigs, are especially difficult to eliminate. However, clinical trials have demonstrated an absence of PERV transmission with a significant reduction in the number of severe hypoglycemic episodes and up to 30% reduction in exogenous insulin doses. A number of methods are currently being tested to overcome the xenograft immune rejection. Some of these methods include the production of various transgenic pigs to better xenotransplantation efficiency and the encapsulation of islets to isolate them from the host immune system. Furthermore, ongoing research is also shedding light on factors such as the age and breed of the donor pig to determine the optimal islet quantity and function.

Keywords: type 1 diabetes, xenotransplant, porcine islets, encapsulation, transgenic

Keypoints

- Preclinical studies show improvements in pig islet survival after transplantation.
- Clinical pig islet xenotransplantation studies prove no transmission of PERV.
- Pig islets can be successfully transplanted using encapsulation technology.
1. Introduction to islet xeno-transplantation

Exogenous insulin is the most common treatment option for type I diabetes (insulin-dependent diabetes mellitus), a chronic metabolic disorder caused by the failure of the beta cells of pancreatic islets most often due to T-cell mediated autoimmune reaction which result in hyperglycemia [1]. While the standard insulin therapy treats patients with diabetes, however, it does not cure the disease, nor does it prevent the development of the secondary complications leading to end stage organ failures along with its morbidity and mortality [2]. Technical advancements in the production of exogenous insulin, better glucose monitoring system and optimal insulin therapy can reduce HbA1C but still has not addressed the issues of increasing hypoglycemic episodes in patients. Achievement of normoglycemia and exogenous insulin independence is the goal of diabetes treatment. The International Diabetes Federation (IDF) estimated the number of adults suffering from DM in 2017 to be 425 million: this number is expected to increase to 629 million patients in 2040 [3]. Whole pancreas and pancreatic islet transplantation
are effective treatment options for diabetes by which insulin independence in T1D patients can be achieved [4]. Unfortunately, both whole organ and cellular transplantation face challenges due to a wide gap between the ever-increasing transplant waiting list and the supply of donor organs [5]. Data from the Organ Procurement and Transplant Network (OPTN) from 2003 to 2015, indicates a 145% increase in the wait list for all organs, while donor availability increased by only 113% (Figure 1) [6]. Similarly, the total number of pancreases available is insufficient to match the need for pancreatic islet allo-transplantation [7–9].

Due to this shortage, xenotransplantation using porcine islets has emerged as a potential alternative source for beta cell replacement. Porcine islets have structural and physiological similarities to human islets. Porcine insulin (differs from human insulin by only one amino acid) is used to treat diabetes in clinical practice [10, 11]. Intact functional islets have been successfully isolated from the pig pancreas [12], and these islets have shown the ability to reverse diabetes when transplanted into NHPs [13]. This review article will present the evolution, current practices, challenges and perspectives for pig islet xenotransplantation.

2. History of islet xeno-transplantation

Xenotransplantation has been attempted for the past 300 years or so and blood xenotransfusion was tried as early as the seventeenth century by Jean Baptiste Denis [14]. This was later followed by corneal transplantations from pigs to humans and kidney transplantations in NHP [15, 16]. The first pancreatic xenotransplantation was performed by Watson et al., implanted three ovine fragments into the subcutaneous plane of a diabetic patient. Though clinically significant blood glucose reduction was not demonstrated, the blood sugar level did decrease [17]. This pioneering work was followed by many experimental xenotransplantations, but results were mostly inconclusive [18–21]. Shumakov et al. reported 53 fetal porcine xenotransplants and 18 fetal bovine xenotransplantations in diabetic patients [22]. A century later, Groth et al. performed clinical xenotransplantation trial using fetal porcine islet cell-like clusters (ICCs) and provided preliminary data regarding the function and survival of grafts. After porcine islets were transplanted into 10 insulin-dependent diabetic kidney-transplant patients, detectable levels of porcine C-peptide were identified in the urine for up to 400 days and in one case, renal graft biopsy showed insulin and glucagon positive cells after staining [23]. Several xenotransplantation studies have also been performed in NHPs [20], and have succeeded in reversing diabetes [24–27] and in reducing daily insulin dosage requirement [28]. Transplanted porcine islet grafts were also shown to survive and function in NHPs for longer than 6 months with immunosuppression [25, 27, 29]. The longest survival rate is now over 603 days according to Shin et al., [30]. Studies have also shown that microencapsulation of the transplanted islets and immune-isolation lead to better survival rate without the need for aggressive immunosuppressive therapy [26].

3. Pig islets as alternative source

The success of porcine insulin and its role in the treatment of T1D has been well established since its discovery in the 1920s [11, 12, 25]. The structural and physiological similarities between human and pig organs, along with its unlimited supply, have made them an excellent translational research model [25]. Insulin extracted from pig islets has been used for the treatment of diabetes for decades [10, 11, 20, 33]. Because porcine islets produce insulin patterns similar to those found in
humans, and because they are readily available [20], studies strongly suggest that islets obtained from pigs could be a promising substitute for human islets in the treatment of T1D. Recent studies on genetically engineered pigs suggest that these pigs are more suitable for xenotransplantation. For example, alpha 1,3-galactosyl-transferase gene knockout (GTKO) pigs, have decreased the incidence of immune-rejection and improved compatibility between the donor and recipient [31–36].

The major advantages for using pigs as an islet source for xenotransplantation are as follows:

1. Ethically acceptable source.
2. The pig pancreas has structural and physiological similarities to the human organ.
3. Unlimited availability.
4. Easy to breed and produce large litters.
5. Rapid growth into adult organs (6 months).
7. Elective and emergent availability of the organs.
8. Low risk of zoonosis.
9. Facilities available to breed pigs under ‘clean’ conditions.
10. Obviates ‘cultural barriers’ to human organ transplant (e.g. Japan); illegal organ trafficking; deleterious effects on organs in brain dead patients; living donor organ donation.
11. Advanced and safe immunosuppression protocols.
12. Cloning and genetic modification of cells to reduce immune destruction.
13. Islet encapsulation to combat immune challenge.

Modified from Ekser et al. [5]; Cooper et al. [37, 38]; Cheng et al. [20].

4. Selection of pig and sources of pig islets

Islet quantity and quality varies with the breed of pigs. Readily available market pigs have shown to yield lower when compared to the well-studied breeds of pigs like Landrace pigs, Chicago Medical School (CMS) miniature pigs and Chinese Wuzhishan (WZS) miniature pigs [23, 25, 27]. Two major factors which have been studied in relation to the source of pig islets for xenotransplantation are the breed and age of the donors. Some well-studied breeds are the Landrace pigs, Chicago Medical School (CMS) miniature pigs, and the Chinese Wuzhishan (WZS) miniature pigs. Market weight pigs are easily available, but studies have shown lower yields than for other breeds [39]. Landrace pigs have been shown to yield large sized (>250 μm) islets with a high islet volume density [39, 40]. Adult Chicago Medical School (CMS) miniature pigs
are bred under specific pathogen-free (SPF) conditions, and contain large-sized islets. The yield is greater than market or other miniature pigs (9589 ± 2838 IEQ/g), making CMS pigs one of the best sources for obtaining islets [39, 41–45]. Another miniature pig, the Chinese Wuzhishan (WZS) pig has also shown an islet yield greater than that of market pigs [39, 46]. Though no consensus has been arrived at the optimal breed for the preclinical/clinical studies, these breeds have been well documented to yield better islets than others. Higher expression of extracellular matrix (ECM) protein in islet capsules makes isolation easier and German Landrace pigs have higher ECM [24].

Additionally, age [43, 44, 47–49] and size of the donor pigs [36, 50–52] are major factors that affect islet isolation outcomes. Some studies have also suggested that gender may play a role in the final islet yield [39, 53, 54]. Pig islets can be obtained at four distinct life-stages: embryonic, fetal, neonatal and adult [55], and Table 1 summarizes the significance, advantages, and disadvantages of pig islets from

<table>

<tbody>
<tr>
<td>Embryonic</td>
<td>In the dorsal pancreatic primordial, strands of insulin positive cells are seen as early as week 4 [43]. From week 13, cells exhibiting intense immunoreactivity for insulin are distributed throughout the pancreas [43, 57].</td>
<td>Embryonic pancreatic tissue exhibit predominantly insulin-positive beta cells without evidence of alpha cells [43, 58]. Use of embryonic primordial pancreas is better than pluripotent stem cells as they do not need steering toward pancreatic differentiation and have lower risk of teratoma [59]. Following transplantation, the exocrine tissue does not proliferate. Hence, there is decreased immune response and inflammatory complications.</td>
<td>Immaturity takes 8–12 weeks (~6 months) for maturation in vivo [43]. Poor insulin response post-transplantation due to immaturity [39, 62–64]. Higher expression of alpha-1,3 galactose (Gal) when compared to adult—more susceptible for humoral rejection. Low yield—only a small number of islets can be isolated, requiring large number of pigs which limits large scale clinical application, with ethical issues.</td>
</tr>
<tr>
<td>Fetal</td>
<td>Porcine islets are isolated from fetuses of 60–69 days gestational age [36, 65]. Islets lack a definite shape and capsule and are organized in clusters (ICCs) [36]. These cellular clusters are composed of &lt;40% endocrine cells (6–8% beta cells) with the majority being the cytokeratin-positive epithelial cells [65]. Their ability to proliferate makes them a potential source of islet cells [27, 36, 66–68]. Isolation process is very simple, involving digestion of the pancreatic tissue to free the islet clusters [65, 69]. No gradient purification necessary. Easily scalable to provide clinical product. Isolation not dependent on the enzyme collagenase, (activity is variable between enzyme lots). The use of alpha 1,3-galactosyltransferase GTKO strains has demonstrated better transplant outcomes than wild-type strains [43, 70].</td>
<td>Isolation process is very simple, involving digestion of the pancreatic tissue to free the islet clusters [65, 69]. No gradient purification necessary. Easily scalable to provide clinical product. Isolation not dependent on the enzyme collagenase, (activity is variable between enzyme lots). The use of alpha 1,3-galactosyltransferase GTKO strains has demonstrated better transplant outcomes than wild-type strains [43, 70].</td>
<td>Cellular culture is required for 5–9 days to form cellular aggregates. Maturity of islets is delayed. Demands higher number of pigs to provide sufficient islets due to lower yield [27, 36, 71]. Because of their clustered appearance, it is difficult to separate islets from the surrounding exocrine and other non-islet cells [36].</td>
</tr>
</tbody>
</table>
different donor life-stages. Adult pigs have been preferred for their higher yield of mature islet cells that have the potential to secrete insulin soon after transplantation. However, the higher costs, fragility of the islets and the difficulty in isolation are the disadvantages. Neonatal and fetal islets are easy and inexpensive to isolate but the main disadvantage is the significant delay in functioning after transplantation due to their immaturity and their high expression of Galactose-α-1,3-galactose (αGal), the major antigenic target for primate anti-pig antibodies [56].

<table>
<thead>
<tr>
<th>Islet source</th>
<th>Significance</th>
<th>Advantages</th>
<th>Disadvantages</th>
</tr>
</thead>
<tbody>
<tr>
<td>Neonatal</td>
<td>The neonatal period is up to 30 days after birth. NPIs are usually obtained from the pancreas within the first week of life [43]. NPIs comprise ~35% of endocrine cells and ~57% of epithelial cells—isclet precursor cells [39, 72, 73]. Correct hyperglycaemia in diabetic animal models as the precursor cells also differentiate and proliferate into beta cells [27, 36, 39, 74, 75]. The cellular aggregates are composed of &lt;40% endocrine cells (20–25% beta cells) with majority being cytokeratin-positive epithelial cells [65]. About 10–13 days after birth, the ICCs begin to resemble adult islets [43, 57].</td>
<td>Isolation process is very simple—the process involves digesting pancreatic tissue simply to free islet clusters [65, 72]. No gradient purification. Easily scalable to provide clinical product. Isolation not dependent on the enzyme collagenase (activity is variable between lots). Isolation process is less expensive than for adult islets. Maintenance of neonates is easy and inexpensive as they are maintained only for few days postpartum. Exhibit strong resistance to inflammatory and hypoxia-induced injury. Lower T-cell reactivity than adult pigs [39, 76, 77]. Potential alternative to adult pig islets as xenografts.</td>
<td>Maturation is delayed when compared to adult islets but is faster than for fetal ICCs. Cellular culture is required for 5–9 days to form cellular aggregates. Lower yield—limits clinical usage. Only 50,000 aggregates can be obtained from a single pancreas when compared to adult.</td>
</tr>
<tr>
<td>Adult</td>
<td>Adult pig islets (APIs) are the major source of islet cells for xenotransplantation [39, 78–80]. APIs are well differentiated with distinct and intact capsule and vasculature with very few insulin positive cells outside these islets [43, 57]. Antigenicity is from N-linked sugars and not from Gal Ag [39, 43, 81–83]. The expression of Gal Ag decreases and becomes negligible as the pig reaches adulthood [43, 81–86]. &gt;2 yrs. is the optimal age [36, 39, 50, 87]. Adult islets are predominantly islet endocrine cells.</td>
<td>Morphologically distinct—can be extracted and purified as a single unit [36]. Mature cells—response to hyperglycemia is immediate following transplantation without latency [36, 39, 87–90]. Insulin independence in diabetic NHPs is achieved when &gt;10,000 IEQs are transplanted. (islets pooled from 2 to 4 adult pigs) [39, 80]. Do not require culturing of the isolated islets [65]. Islet yield is greater than for fetal and neonatal pigs [43, 78, 91].</td>
<td>Isolation is technically challenging, complex and expensive [36, 43, 65, 79, 92–94]. More fragile islets [65]. Difficult to scale-up [65]. Highly dependent on the enzyme lot and activity [65]. Requires gradient purification [65]. Very high cost of maintenance and breeding in a clean isolated environment [36, 43, 47]. Bigger size of the animal is associated with surgical complications during organ procurement [36, 50].</td>
</tr>

Table 1. Different sources of pig islets; significance, advantages, and disadvantages.
5. Pig islet isolation

Adult pig islet preparation is very similar to human islet isolation methods [55] but the digestion process is a lot more gentle as the porcine islets are extremely fragile. Methods of islet preparation may vary depending on the life-stage of the donor pancreas. Fetal pig ICCs and neonatal pig islets (NPIs) are immature cells and can be easily isolated by enzymatic digestion [55] but must subsequently be cultured prior to transplantation to promote re-aggregation of islet clusters and to help eliminate exocrine cells [55]. The digestion procedure for the adult pig pancreas is significantly different over the fetal or neonatal pancreas. Many factors, such as the type of donor pigs, blood exsanguination, warm ischemia time, cold ischemia time, enzyme lot and activity, perfusate, and the isolation-purification process significantly affect the final islet yield, function and viability [39, 54, 55, 79, 95–97].

5.1 In vitro and in vivo assessment of pig islet function

In vitro studies investigating the insulin response of islets from donor pigs of different ages have shown that the insulin response from adult pig islets is more pronounced and sustained, and that they have a higher stimulation index over young pigs [36]. Islets from different age of donor pigs have also been compared in vivo. Two groups of diabetic nude mice populations were implanted with either young and young adult porcine islets or adult islets. One out of 11 recipients of young and young-adult islets achieved normoglycemia, whereas 32 out of 39 transplanted with adult islets became normal, the blood glucose reaching normal range within 4 weeks post-transplantation. Graft function was confirmed as the cause for normoglycemia, as all 32 mice reverted back to hyperglycemia after islet graft removal [36]. Many studies using NHP models have demonstrated the benefits of the pig islets as xenotransplants, with a potential cure for diabetes [25, 39, 98–101]. These studies have shown diabetes reversal with prolonged graft survival in diabetic NHPs.

5.2 Hurdles for xenotransplantation

Prevention of the transmission of porcine endogenous retrovirus (PERV) and immunological reactions have been the major hurdles for xenotransplantation in preclinical and clinical trials. Though the risks of zoonosis have been downplayed significantly with the introduction of genetically modified pigs, immunological responses like instant blood mediated inflammatory response (IBMR) dictate the success of the graft survival. One of the most important risk to overcome during xenotransplantation is the prevention of zoonosis [102]. Porcine endogenous retroviruses (PERVs) are of special concern as they are found integrated with porcine genomes and are difficult to eliminate [102]. The degree of risk of PERV being able to infect the human host is unknown, but evidence has shown that PERV can infect human cells when co-cultured with human EK-293 cells [55, 103]. Cross-species transmission has also been documented in pig to SCID mice xenotransplantation [55, 104]. However, no evidence of transmission has been documented in T1D patients who received porcine islet transplants, even after prolonged follow-up [55, 105].

Apart from PERV, other pathogenic organisms including the herpes virus, lymphotropic herpes virus, and cytomegalovirus can also be transmitted. [55]. Methods of combatting these pathogens include careful assessment and screening protocols, designated pathogen-free (DPF) breeding and housing of PERV gene knockout pigs, all of which can help minimize the risk of zoonotic infections [29]. DPF herds
5.3 Immunological response

Pig islet cells express different surface proteins that play a major role in the immunological rejection seen following transplantation [102, 107]. Immunological responses are much more complex than seen in allo-transplantation [102]. Immune mediated inflammatory response have been brought down by significantly by genetic modifications as summarized in Table 2. Hyper acute rejection (HAR), Instant blood mediated inflammatory response (IBMIR), and cellular rejection are the types of responses seen in graft rejection of which IBMIR is the most crucial. Portal vein site provides good revascularization and drainage for islet transplantation but due to the severe complications like bleeding, thrombosis, and hepatic steatosis, it is no longer an optimal site [108]. Immunological issues observed during xenotransplantation are similar to those seen in allo-transplantation but are much more complex [102]. Pig islets express different types of surface proteins, and these play a critical role in the immunologic rejection seen following transplantation [107]. Multiple genetic modifications in pigs have been proposed to significantly reduce immune mediated inflammatory response, and these are summarized in Table 2.

There are four known major routes for islet cell loss following transplantation and these are summarized in the following sections.

5.3.1 Hyper acute rejection (HAR)

HAR occurs due to the presence of pre-existing host antibodies to surface proteins on the porcine islets. These surface proteins can be broadly categorized into Gal and non-Gal proteins [34, 38, 110]. The Gal epitope is absent in humans, apes and old-world monkeys but many bacteria, NHP and new world monkeys express

must be free from a comprehensive and list of specified microorganisms [29, 106] and meticulous documentation and standard operating procedures (SOPs) must be implemented to maintain this status [29] including feed restrictions [29].
the Gal epitope abundantly. In pigs, the expression of Gal antigens decreases as they grow into adults [84, 102, 110, 124, 125].

As the human body is continuously exposed to micro-organisms (including bacteria), it develops immunity to the Gal antigen and has pre-formed, circulating anti-Gal antibodies [107, 126], which make up around 1% of the circulating antibodies [102, 124]. Once the pigs islets are transplanted, these pre-formed antibodies kill the islet cells rapidly by complement mediated destruction [107, 124] resulting in substantial islet loss [102, 107, 127].

Antibodies are also produced for other surface epitopes (non-Gal Ag) such as N-glycolylneuraminic acid (NeuGc) also known as Hanganutzu-Deicher and beta 1,4 N-acetylgalactosaminyltransferase (B4GALNT2) [107, 128–130] which are also involved in complement mediated destruction of xenografts [107].

There are two known strategies for prevention of HAR. Knockout of genes responsible for adding the Gal epitope and other epitopes such as Neu5Gc to the cell surface can prevent their expression [34, 102]. Secondly, expression of complement regulatory proteins such as hCD46, hCD55 and hCD59 can be induced on the surface of the islet cells [102, 131]. Double knockout pigs (deficient in alpha-gal (GTKO) and Neu5Gc) have been produced, which has significantly reduced the incidence of humoral rejection [102, 132]. The Gal antigen is highly expressed in fetal and neonatal pig pancreas, but its expression decreases as the pigs reach adulthood. The use of GTKO pigs is more validated when using fetal or neonatal pancreas [85, 116], but is not as essential when using adult pigs [116]. However, increasing titres of anti-Gal IgG antibody have been noted when immunosuppression is stopped after adult pig islet transplant [30, 116], so GTKO pigs may prove beneficial even for islets isolated from adult pigs.

5.3.2 Instant blood mediated inflammatory reaction (IBMIR)

Following the intra-portal infusion of the pig islets, the elevated expression of tissue factor by the islets initiates IBMIR [39]. The IBMIR contributes to significant islet loss in the early post-transplant phase through a series of events involving simultaneous complement activation (alternative pathway) [81, 86], activation of intrinsic and extrinsic coagulation pathways, and platelet activation (platelet aggregates around the islets P6) followed by neutrophil and monocyte infiltration [110, 116, 133, 134]. IBMIR can result in 60–80% of islet loss in the immediate post-transplant period [39, 55, 110, 118, 135], but studies in NHPs have shown that if a sufficient number of islet cells survive, they can establish normoglycemia for several months [110]. Genetically modified pigs have been produced [110, 136] to combat IBMIR by decreasing the load of xenoantigens but it failed to provide long-term protection against host response [137]. Experimental studies involving control of complement activation by cobra venom factor, and platelet aggregation and coagulation by anti-platelet agents and low molecular weight heparins are not proven clinically safe, [138, 139]. Peritoneal cavity and omentum offer alternative sites for transplantation of encapsulated islets [140].

5.3.3 Cellular rejection

Cellular rejection, a CD4+ T-cell-dependent process [55, 141–143], plays a major role in islet destruction [39, 118, 144, 145]. Acute cellular rejection occurs within 24 h to 20 days post-transplant, and is characterized by a massive infiltration of macrophages and T-cells (CD4+ and CD8+ cells). Two signaling pathways required for the full activation of T cells are the T cell receptor signaling, and the co-stimulatory signaling [55, 146]. Since T cell activation requires double signaling...
involving TCRs and co-stimulatory molecules [39], blockade of co-stimulatory cell surface molecules such as CD80/86-CD28 and/or CD40L (CD154)-CD40 have significantly improved graft survival, even without immunosuppression [39, 147–149]. The addition of targeted immunosuppression to multi-molecular blockade may further increase effectiveness, and provide an even more promising option to prevent cellular destruction of the transplanted islets [39].

5.3.4 Islet cell revascularization

Islet revascularization is critical for the survival of transplanted pig islets. Islet grafts are cut off from their native vascular supply and after transplantation, are solely dependent on diffusion for nutrient supply, until functional revascularization is established with the host vasculature. This process takes place within 10–14 days post-transplantation [41, 49, 141].

6. Islet encapsulation approaches

Islet encapsulation provides the means for islet cell survival in the absence of immunosuppressive drugs. The principle of encapsulation is that transplanted cells are contained within an artificial compartment separated from the immune system by a semipermeable membrane. The capsule should protect the cells from potential damage caused by antibodies, complement proteins, and immune cells. Therefore, the capsule is often referred to as an “immunoisolation device.” As well as the protective mechanism provided by the capsules, islet cells within the capsules can also release insulin to control blood glucose levels, since this membrane enables small molecules to diffuse in (glucose, oxygen, and nutrients) and out (metabolic wastes) [39, 150–152]. Thus, the encapsulation system is also regarded as a “bio-artificial pancreas.” The immunoisolation device or bioartificial pancreas can be commonly separated into two categories, intravascular and extravascular devices. The latter can further be divided into macroencapsulation and microencapsulation devices. Intravascular and extravascular classifications are based on whether or not it is connected directly to the blood circulation.

The macroencapsulation and microencapsulation classifications depend on whether it contains one or more islets in the device [153, 154]. Alginate is the most commonly used capsule material for microencapsulation, but other materials such polyethylene glycol have also been tested [153].

Although the capsule is selectively permeable, islets can be damaged due to hypoxia or inadequate nutrients, and slow glucose and insulin diffusion can delay insulin response to changing glucose levels [155]. Despite the protection offered from direct immune attack, islets can still be damaged by immune responses. Inflammatory cytokines, produced against the capsules can enter the capsule and damage islets. The encapsulated islets themselves may release such cytokines and cause self-damage [156]. Approaches investigated to overcome these problems include testing different sites of implantation, creating biocompatible capsules, and optimizing the capsule size. The use of genetically engineered pig islets within capsules to promote graft survival and function have also been studied [156].

Several clinical trials of encapsulated pig islets to improve long-term survival outcomes of xenografts are currently being conducted around the world [117, 157]. A phase I/IIa clinical study in Moscow has tested the clinical applicability of a commercially available encapsulated pig islet product called Diabecell [39, 158, 159]. Additional phase I/IIa clinical trials are ongoing in New Zealand and Argentina. These trials have demonstrated an absence of PERV transmission, a significant
Porcine Islet Cell Xenotransplantation
DOI: http://dx.doi.org/10.5772/intechopen.90437

reduction in the number of severe hypoglycaemic episodes and up to 30% reduction in exogenous insulin doses [29, 160]. A 10 year follow up of another study involving xenotransplantation of encapsulated porcine islets into the peritoneum of a T1D patient has shown long-term islet survival and function, with no evidence of PERV infection [39, 150].

7. Regulatory aspects

Any new therapeutic substance or procedure, safety and efficacy of the drug substance have been inveterate before starting government approved clinical trials. In line with guidance in consensus statements from the International Xenotransplantation Association and the WHO on xenotransplantation, geographical location will impact choice of the microbiological mitigation strategy. Risk management at the source would include the definition of pathogens circulating in the countries of origin [161], establishment of reliable detection, and screening methods and assessment of risk from animal feed. Given the source animals to be utilized will be from specific pathogen-free/designated pathogen-free or high hygienic herds from a single location, the pathogen risk compared with standard slaughter herd animals is significantly reduced. Further testing during the manufacturing process, that is, islet isolation and encapsulation will provide tissue specific data that should further confirm safety of the final product. Moreover, alginate encapsulation allows keeping the islets in culture for longer periods thus giving enough time to perform viral screening on islet products before transplantation. Other release quality controls related to islet morphology, viability, purity, quantity, and potency should also be established in order to guarantee that only well characterized and functional islet preparations are used in patients. The use of genetically modified donor pigs to reduce islet cells immunogenicity and improve their secretory function stipulates that these genetic modifications should be well characterized. Integration of transgene expression cassettes should be in well-defined genomic locations, preferably in the form of a single-targeted integration that would ensure stable expression of the transgene across herds without affecting other cell functions or rendering them tumorigenic. In this context, it should be noted that encapsulation limits the risk of tumor cells spreading since it confines the cells and eliminates the need for immunosuppression meaning that in case the integrity of the encapsulation device would be compromised, xenogeneic pig cells would most probably be rejected by the host immune system. The use of nonhuman primates in research is subjected to very strict ethical and regulatory considerations but the pig-to-primate model is still considered as a gold standard for pig islet xenotransplantation, so that safety and efficacy data obtained using this model are required before initiating clinical studies [162].

8. Conclusion

Porcine islets represent an excellent alternative source to replace human islets in diabetic patients. Pig islets can be obtained from different life-stages (embryos to adults) and has several other advantages making it an indispensable resource for xenotransplantation. Active research have resulted in standardization of protocols, thereby bettering isolation outcomes. In addition, incorporation of multiple strategies such as generating transgenic pigs together with developing cellular and molecular therapies to sustain long-term xenograft survival have brought porcine islets closer to clinical applications. Despite the risk of zoonosis and other factors which
contribute to islet loss post-transplantation, tremendous progress has been made within the field such as developing encapsulated islets to combat host immunity and utilizing host stem cells to aide islet revascularization. Pig islet xenotransplantation currently acts as a bridge between allo-transplantation and stem-cell therapies. With all the tremendous progress made within the field, ongoing research focuses on a better understanding of various factors such as donor characteristics, isolation procedures, microbiological safety, and immunological tolerance to improve pig islet yield, function and transplantation outcomes. Furthering this understanding will require multiple clinical trials directed toward establishing porcine islets as a safe, effective and robust alternative for treating patients with T1D.

Acknowledgements

The authors sincerely thank Kentucky Organ Donor Affiliates (KODA) for the supply of human pancreases for our research programs.

Conflicts of interest

None.

Financial support and sponsorship

The authors thank the Jewish Heritage Fund for Excellence for providing generous support to our program.
