Radiation Doses and Risk Assessment during Computed Tomography of the Chest in COVID-19 Patients

Elena Ivanovna Matkevich and Ivan Vasilievich Ivanov

Abstract

Accounting for the effective dose (ED, mSv) and calculating the radiation risk during CT is necessary to predict the long-term consequences of radiation exposure on the population. We analyzed the results of 1003 CT examinations of the chest in patients with suspected COVID-19 in the city diagnostic center. The average ED and confidence intervals (p ≤ 0.05) for patients with a single CT scan were: children (12–14 years) 2.59 ± 0.19 mSv, adolescents (15–19 years) 3.23 ± 0.17 mSv, adults (20–64 years), 3.43 ± 0.08 mSv, older persons (65 years and older) 3.28 ± 0.19 mSv. The maximum radiation risk values were 31.2×10⁻⁵ in women children and 29.3×10⁻⁵ in women adolescents, which exceeds the risk values for men in these age groups by 2.3 and 1.9 times, respectively. For the group of adult patients the risk was 11.2×10⁻⁵ in men and 17.4×10⁻⁵ in women, which is 1.6 times higher than in men. All these risk values are in the range of 10⁻⁵–10⁻⁶, which corresponds to the level LOW. For the group of older age patients, the radiation risk was 2.6×10⁻⁵, which corresponds to the level of 1×10⁻⁵–10⁻⁶, VERY LOW. Our materials shows in detail the technique to evaluate effective radiation doses for chest CT and calculate the radiation risk of the carcinogenic effects of this exposure.

Keywords: computed tomography, chest CT diagnostics, effective dose, radiation risks levels, the dependence of the radiation risk levels of sex and age

1. Introduction

In the coming years, due to the introduction of methods of medical diagnostics and treatment using ionizing radiation, the growth of medical exposure of the Russian population expected to continue, especially due to computed tomography (CT). Therefore, it is important to evaluate radiation dose levels and population radiation risks in the form of a possible oncological pathology among the population in the long term after exposure [1–8].

Estimating the stochastic effects on the basis of a linear non-threshold model, P. Galle [9] concluded that, compared to 700,000 spontaneous cancers per year, when recalculated to the French population, 7,000 deadly cancers are caused by radiation causes. Of these, 3,000 are associated with high concentrations in radon homes, 1,000- with radiation medical procedures, 10 - with radiation from the work of the
nuclear industry and from increased natural radiation background. Therefore, from medical exposure, 14.3% of all radiation-related oncological pathologies arise. Due to the widespread use of CT of the chest organs for the diagnosis of COVID-19, including during repeated examinations, this issue is of particular relevance. The aim of the study was to assess effective radiation doses for chest CT for the diagnosis of Covid-19 and calculate the radiation risk of the effects of this exposure.

2. Material and methods

2.1 General characteristics of patients

We analyzed the results of 1003 CT examinations of the chest performed in patients with suspected COVID-19 during one week in October 2020 in the city diagnostic center. Among these patients were 6.2% children in the ages of 12–14 years old, 15.3% adolescents in the ages of 15–19 years old, 60.1% adults in the ages of 20–64 years old, and 18.4% older persons of ages 65 years and older. The average ages and confidence intervals (p ≤ 0.05) were 13.8 ± 0.20 years old in group 1 (children), 17.1 ± 0.41 years old in group 2 (adolescents); 45.8 ± 1.47 years old in group 3 (adults) (of which 41.8% are of ages 20–45 years old and 58.2% are of ages 46–64 years old); 69.4 ± 1.79 years old in group 4 (older persons). The percentage number of male (female) persons in the groups are 51.6% (48.4%) in group 1, 52.3% (47.7%) in group 2, 46.3% (53.7%) in group 3, 47% (53%) in group 4. The proportion of patients with CT signs of pneumonia and without pathological signs amounted to a total of 54.6% and 45.4%, respectively, for each of the four age groups. The distribution of the patients into groups during CT examination is given in Table 1.

Table 1. The distribution of patients in groups during CT examination on COVID-19.
2.2 Description of computed tomography technique, calculation of effective dose and radiation risk

CT studies of the chest were performed on a Siemens Somatom Emotion 16 scanner (16-slice) using a standard algorithm. The voltage on the tube was 130 kV with automatic modulation of the amperage; the slice thickness was 0.8 mm (pitch 1.4) or 1.5 mm (pitch 1.2). Of each patient, the values of the parameters determining the radiation load were entered into the database CTDI\textsubscript{vol} (mGy), DLP (mGy*cm) and ED, mSv.

The calculation of the effective dose (ED, mSv) for a single phase CT scan was performed according to the following equation:

\[ \text{DLP (mGy} \times \text{cm)} = \text{CTDI}\text{vol (mGy)} \times \text{irradiated length (cm)} \quad (1) \]

The procedure for registering the indicator “irradiated length (cm)” was as follows. Previously, the X-ray technician performed an X-ray (tomogram) of the chest. Then the region of interest (ROI) was installed on the CT scanner console in accordance with the Recommendations of EUR16262, 1999 [10]: Volume of investigation (routine chest) - from lung apex to the base of the lungs. The length of this area (irradiated length) was measured individually in each patient. In this area, a CT scan was subsequently performed and, accordingly, the patient was irradiated. DLP was calculated for this zone.

In our study, for the chest the “irradiated length” (Median, 25th and 75th percentile) was (cm): 31.3 (30.1–33.4) - in children, 34.7 (32.6–36.6) - in adolescents, 36.6 (34.9–38.7) - in adults, 33.3 (31.6–36.8) – for persons 65 years and older.

Then, using the DLP, the effective doses was estimated according to the formula [11]:

\[ \text{ED, mSv} = K_{\text{ED DLP}} \times \text{DLP}. \quad (2) \]

To calculate the effective dose (ED, mSv) the chest $K_{\text{ED DLP}}$ conversion factor (mSv*mGy\textsuperscript{-1}*cm\textsuperscript{-1}) used was $K_{\text{ED DLP}} = 0.012$ for both the children group (12–14 years old) and the adolescent group (15–19 years old) and $K_{\text{ED DLP}} = 0.016$ for the subjects older than 19 years [12, 13].

The method of calculating the risk of radiation consequences is based on the analysis of the frequency of leukemia and other oncological diseases, hereditary disorders in subsequent generations in the population after irradiation of people during the atomic explosions in Hiroshima and Nagasaki, the Marshall Islands, after gamma irradiation of patients with cancer and after incidents and accidents at nuclear reactors. Several hundred publications with this information were summarized in ICRP Publication 103, 2007 [11], and the risks of these consequences in persons of different genders and ages were calculated depending on the radiation dose received. In our study, calculations of radiation risk are carried out according to the National Methodological Recommendations [14] as follows:

\[ R = \text{ED} \times r, \quad (3) \]

where

R is the radiation risk per 100,000 population at an exposure dose of ED, mSv;
ED - effective dose, mSv;
r - risk indicator for exposure of 1 mSv (mSv\textsuperscript{-1}).
A risk indicator for exposure of 1 mSv used, lifetime cancer risk of radiation is $5.5 \times 10^{-5}$ mSv$^{-1}$ for the entire population regardless of age and sex. However, in this study $r$ (risk indicator) were used, taking into account the age and sex of patients (Table 2) in accordance with the National Methodological Recommendations [14]. These values were calculated for the Russian population (mortality and morbidity data for 2008) using risk models and ICRP calculation methods [11, 15].

When calculating Radiation risk level, the scales listed in Table 3 were used.

Table 3. The radiation risk levels (individual lifetime risk) to a patient’s health associated with medical exposure during diagnostic studies or treatment procedures [14].

A risk indicator for exposure of 1 mSv used, lifetime cancer risk of radiation is $5.5 \times 10^{-5}$ mSv$^{-1}$ for the entire population regardless of age and sex. However, in this study $r$ (risk indicator) were used, taking into account the age and sex of patients (Table 2) in accordance with the National Methodological Recommendations [14]. These values were calculated for the Russian population (mortality and morbidity data for 2008) using risk models and ICRP calculation methods [11, 15]. When calculating Radiation risk level, the scales listed in Table 3 were used.

The mean and median values of effective doses in the formed groups were close, the assessment of the data according to Kolmogorov–Smirnov test for normality and Shapiro–Wilk’s W test showed that the nature of their distribution is close to normal. The measured data were expressed as the average ± confidence interval (X ± CI) at p ≤ 0.05, as well as median (Me, 25th and 75th percentile). The significance of differences between the groups according to Student t-criterion, P value < 0.05 was considered for statistical significance. STATISTICA statistical software (version 10.0; Stat Soft. Inc., United States) was used for analysis.

3. Results and discussion

The average effective doses to patients with a single CT scan in the formed groups as illustrated in Table 4 and Figure 1A were $2.59 \pm 0.19$ mSv in group 1 (children 12–14 years old), $3.23 \pm 0.17$ mSv in group 2 (adolescents 15–19 years

<sup>*</sup>Significance of differences mean values ED (X) between groups (p ≤ 0.05) 1 and 3, 2 and 3, 1 and 4, 2 and 4.

Table 4.
Effective doses and their compliance with radiation risk levels in patient groups with a single CT scan of the chest on COVID-19.
old), 3.43 ± 0.08 mSv in group 3 (adults 19–64 years old) and 3.28 ± 0.19 mSv in group 4 (older persons – 65 years and older).

These doses are comparable with the ED values shown in the report [16] on the evaluation of DRLs for adult CT in European countries and in studies of other authors [17–19]. The DRLs for CT of adult chest organs in European countries were: 4.7–6.31 mSv in Netherlands [11, 14], 5.1–5.95 mSv in Germany [16, 18], 6.8 mSv in Austria [16], 5.95–10.4 mSv in Great Britain [16, 19], 7.31 mSv in Finland [16], 8.5–10.5 in Denmark [16], as well as 7.65 mSv in Australia [20].

In our earlier study [21], with standard protocols on different CT scanners, the values of the ED were in the ranges of 2.4–6.04 mSv and 8.4–15.33 mSv, for a single-phase and multiphase with contrast CTs, respectively. The use of low-dose protocols (tube voltage from 80 to 100 kV with automatic modulation of current) made it possible to reduce the ED to 1.6 mSv, when applying the iterative reconstruction algorithm MBIR for single-phase CTs and to 4.41 mSv when applying the iterative reconstruction algorithm ASIR for multiphase CTs [22].

Based on the risk indicator value for exposure of 1 mSv with age and sex (Table 3) were calculations radiation risk values and radiation risk levels after chest CT radiation per 100,000 exposed persons (Table 4). The maximum radiation risk values for a single CT were observed (Figure 1B) in groups of children (24.1*10⁻⁵) and adolescents (23.3*10⁻⁵). As can be seen in Figure 2B, the radiation risk values for a single CT were 31.2*10⁻⁵ in women children (12–14 years old) and 29.3*10⁻⁵ in women adolescents (15–19 years old), which exceeds the risk values for men in these groups by 2.3 and 1.9 times, respectively. For the group of adult patients the
average risk was $14.4\times10^{-5}$, $(11.2\times10^{-5})$ in men and $17.4\times10^{-5}$ in women, which is 1.6 times higher than in men. Nevertheless, all these risk values are in the range of $10^{-5}-100\times10^{-5}$, which corresponds to the level LOW. For the group of older age patients, the radiation risk was $2.6\times10^{-3}$, which corresponds to the level range of $1\times10^{-5}-10\times10^{-5}$, VERY LOW.

We have compared the calculations with estimates of radiation risks in other studies.

For example, when planning the limits of exposure of astronauts [23], the risk of oncological diseases and genetic effects are rather low: $0.2\times10^{-6}$ for leukemia, $0.2\times10^{-6}$ for other types of malignant neoplasms, and $0.05\times10^{-6}$ for genetic effects, per year per dose of additional irradiation of 1 mSv. Spontaneous incidence are
50*10^{-6} for leukemia, 1000–2000*10^{-6} for other types of malignant neoplasms and 8000*10^{-6} for genetic effects per year.

In publication 103 of the ICRP [11], new views of the ICRP on the principles and approaches to ensuring radiation safety, are formulated in comparison with the previous document - Publication 60 of the ICRP [15]. Epidemiological data obtained since the publication of Publication 60 of the ICRP served as a reason for revising the values of the nominal risk factors per unit dose for radiogenic cancers and hereditary effects (Table 5).

As we can see, the new risk values in Publication 103 are slightly lower as those specified in Publication 60. But, at the same time, for children compared with adults, they were increased in terms of Malignant neoplasms from 1.5 to 1.68, for hereditary defects from 2.25 to 3.0, and in the total number of negative effects from 1.61 to 2.0. Our results are comparable to these guidelines.

I.A. Tsalafoutas, G.V. Koukourakis [24] emphasize that stochastic negative effects can be caused even by small doses of radiation, and give the following example of calculating the risk associated with radiation during CT. The assumption of a 5% probability of risk per 1 Sv (1,000 mSv) for the occurrence of cancer or hereditary effects means that the examination, which leads to patient exposure in ED = 10 mSv (typical for CT of the abdomen and pelvis), implies 0.05% chance of such risks. That is, for every 10,000 patients, who underwent CT with a dose of 10 mSv, five people can be expected, to develop cancer or hereditary effects as the result of radiation.

There was calculation individual of effective dose and risk of malignancy based on Monte Carlo simulations after whole body CT [25]. The Excess Relative Risk (ERR\textsubscript{MC}), as a measurement of the exceeding risk of an exposed person compared to a non-exposed person, calculated using the solid cancer mortality in the United States as baseline (female: 17,500/100,000; male: 22,100/100,000).

There was calculation individual of Effective Dose and estimation of organ-specific additional Lifetime Attributable Risk (LAR) of cancer mortality after Whole Body Computed Tomography based on Monte Carlo simulations and report VII about Biologic Effects of Ionizing Radiation (BEIR VII). Considering the effective doses of 1.48 ± 0.15 mSv for the lungs, the LAR for mortality from lung cancer \([n / 100,000]\) was 13.25 ± 4.24.

In our study, it was shown that with a single chest CT scan in patients with suspected COVID-19, additional (to a spontaneous level) cases of oncological pathology per 100,000 people may occur: 24.1 cases in children, 23.3 cases in adolescents, 14.4 cases in adults, 2.6 cases in older persons.

The average effective dose will increase in proportion to the increase in the number of CTs performed on the patient from 2.6–3.4 mSv with a single CT scan to the calculated values of 7.8–10.3 mSv with three times CTs. This will lead to a threefold increase in radiation risks to levels per 100,000 people may occur

Table 5. Comparison of the risk of negative effects of exposure from a dose of 1 mSv, number of cases per 10\(^3\) people (ICRP Publication 103, 2007 [11]; ICRP Publication 60, 1991 [15]).
(Figure 1B): 72.3 cases in children, 69.8 cases in adolescents, 43.2 cases in adults, 7.9 cases in older persons. Due to the increased post-radiation risks in children; currently, both the European and the American Society of Pediatric Radiology do not recommend the use of CT to diagnose COVID-19 pneumonia in children. CT is indicated only for severe, where concurrent pathology need to be excluded.

In men, the average radiation doses in the four age groups were slightly higher than in women (Figure 2A). However, with an increase in the number of CT scans from one (Figure 2B) to two (Figure 2C) and up to three (Figure 2D) in females, the increase in the calculated radiation risk compared to men is more significant, especially in women children (in 2.3 times) and among women adolescent (in 1.9 times). The radiation risk in men and women in all subgroups by age up to 65 years remains at the LOW level ($10^3$–$10^5$), and in the older subgroup at the VERY LOW level ($10^2$–$10^5$). However, with a three-fold CT scan in groups of children and adolescents, the radiation risk in women approaches the border of the MODERATE level ($10^5$–$300*10^5$), and in the old group to the border of the LOW level ($10^3$–$100*10^5$).

By evaluating the lung irradiation with the doses used in the ongoing clinical trials to treat COVID-19 patients, our data shows that a radiation dose 0.5 Gy provides an acceptable Risk Identification Checklist (RIC) estimate (LAR 1%), irrespective of sex and age at exposure [26]. However, a promising direction is the use of modern CT scanners, which allow the use of low-dose algorithms for CT diagnostics [27], while significantly reducing the radiation exposure to patients.

4. Conclusions

Because the study established effective radiation doses for chest CTs of patients with the diagnosis of COVID-19, the radiation risks for a single, double and triple chest CTs in different age and sex of patients were calculated. It has been found, that the radiation risk due to a single, double and triple chest CTs for patients under 65 years old is LOW, and for 65 years old and older patients is VERY LOW. Taking into account the radiation risk during CT is necessary to reduce the long-term consequences of radiation exposure on the population.
