Propagation of Electromagnetic Waves in Thin Dielectric and Metallic Films

Luc Lévesque
Royal Military College of Canada
Canada

1. Introduction

Matrix formalism is a very systematic method to find the reflectance or transmittance in a stratified medium consisting of a pile of thin homogeneous films. Fitting experimental values of reflectance curve to expressions obtained from the matrix formalism method is an efficient method to estimate the refractive index (n) of a dielectric and/or the real and imaginary parts of a metal permittivity (ε). In the next section, the method of matrix formalism is briefly reviewed with some examples to show how it can be applied in curve fitting to determine refractive indices or the metal permittivity. Applications to more complex structures such as planar waveguides and periodic grating are presented in sections 2 and 3, respectively.

1.1 Matrix formalism for the transverse electric and magnetic waves in stratified thin films

Maxwell equations will be applied at each interface between two homogeneous media to find the characteristic matrix defining a thin film. Let us consider figure 1 for a transverse electric (TE) wave with the E-field vector perpendicular to the plane of incidence for one thin homogeneous film.

Fig. 1. Electric field (E) and magnetic field (H) in each medium of refractive index n₁, n₂ and n₃.

\[
\begin{align*}
E₁⁺ &= E₁ - E₁응
E₁⁻ &= E₁ - E₁응
E₂⁺ &= E₂ + E₂응
E₂⁻ &= E₂ + E₂응
H₁⁺ &= \frac{E₁}{μ₀} - \frac{E₁응}{μ₀} \cos θ₁
H₁⁻ &= \frac{E₁}{μ₀} - \frac{E₁응}{μ₀} \cos θ₁
H₂⁺ &= \frac{E₂}{μ₀} - \frac{E₂응}{μ₀} \cos θ₂
H₂⁻ &= \frac{E₂}{μ₀} - \frac{E₂응}{μ₀} \cos θ₂
\end{align*}
\]
In figure 1, the H-field is related to the E-field using:

\[ H_{i,r,t} = \frac{\varepsilon_0 \mu_0 n_{i,r,t}}{\mu_0} E_{i,r,t} \]  

(1)

where \( \varepsilon_0 \) and \( \mu_0 \) are referred to as the electric permittivity and the magnetic permeability, respectively. Letters \( i, r \) and \( t \) stand for incident, reflected and transmitted rays, respectively and the homogeneous medium is identified using numbers 1, 2 or 3.

As both the E and H fields are continuous at boundary 1, one may write \( E_1 \) and \( H_1 \) as:

\[ E_1 = E_1' = E_{i1} + E_{r2} \]  

(2)

\[ H_{1i} = H_{1r} = n_2 \sqrt{\frac{\varepsilon_0}{\mu_0}} (E_{i1} - E_{r2}) \cos \theta_2 = Y_2 (E_{i1} - E_{r2}) \]  

(3)

where

\[ Y_2 = n_2 \sqrt{\frac{\varepsilon_0}{\mu_0}} \cos \theta_2 \]  

(4)

The system of equations (2) and (3) can be written under the matrix form as:

\[
\begin{bmatrix}
E_1 \\
H_{1i}
\end{bmatrix} = \begin{bmatrix}
1 & 1 \\
Y_2 & -Y_2
\end{bmatrix} \begin{bmatrix}
E_{i1} \\
E_{r2}
\end{bmatrix}
\]  

(5)

At interface 2, we merely write

\[ E_2 = E_2' = E_{i2} + E_{r2} \]  

(6)

By making use of the E-field amplitude phase shift, it can be shown that \( E_{i2} \) and \( E'_{i2} \) can be expressed as:

\[ E_{i2} = E_{i1} e^{-j\beta_2} \]  

(7)

and

\[ E'_{i2} = E_{i2} e^{-j\beta_2} \]  

(8)

respectively, with

\[ h_2 = d_2 \cos \theta_2 \]  

(9)

where \( d_2 \) is the thickness of the homogeneous thin film and \( \theta_2 \) is the angle defined as shown in figure 1. \( k_2 \) is the wave-vector in the thin homogeneous film (medium 2), which is given as

\[ k_2 = \frac{2\pi}{\lambda} n_2 \]  

(10)

where \( \lambda \) is the wavelength of the monochromatic incident light when propagating in a vacuum.
Equations (7) and (8) are used to express the tangential component of the H-field vector at interface 2 as:

\[ H_{2z} = Y_2(E_{1z}e^{-jk_{1z}h_2} - E_{2z}e^{jk_{2z}h_2}) \]  

(11)

Using Equations (7) and (8), Equations (6) and (11) are expressed under the matrix form and by matrix inversion one can show that:

\[
\begin{bmatrix}
E_{1z} \\
H_{1z}
\end{bmatrix}
= 
\begin{bmatrix}
cos(k_{2z}h_2) & j\sin(k_{2z}h_2) / Y_2 \\
Y_2j\sin(k_{2z}h_2) & \cos(k_{2z}h_2)
\end{bmatrix}
\begin{bmatrix}
E_{2z} \\
H_{2z}
\end{bmatrix}
= M_2
\begin{bmatrix}
E_{2z} \\
H_{2z}
\end{bmatrix}
\]

(12)

Lastly, substituting Equation (12) into Equation (5) the E and H field components at interface 1 are related to those at interface 2 by:

\[
\begin{bmatrix}
E_{1z} \\
H_{1z}
\end{bmatrix}
= 
\begin{bmatrix}
cos(k_{3z}h_3) & j\sin(k_{3z}h_3) / Y_3 \\
Y_3j\sin(k_{3z}h_3) & \cos(k_{3z}h_3)
\end{bmatrix}
\begin{bmatrix}
E_{3z} \\
H_{3z}
\end{bmatrix}
= M_3
\begin{bmatrix}
E_{3z} \\
H_{3z}
\end{bmatrix}
\]

(13)

The 2x2 matrix in equation (13) is the characteristic matrix \( M_2 \) of the homogenous thin film. Note that \( M_2 \) is unimodular as its determinant is equal to 1. Assuming another film lying just underneath the thin film shown in figure 1, from Equation (13) we imply that field components E and H at interface 2 will be related to those at interface 3 by the matrix equation:

\[
\begin{bmatrix}
E_{2z} \\
H_{2z}
\end{bmatrix}
= 
\begin{bmatrix}
cos(k_{4z}h_4) & j\sin(k_{4z}h_4) / Y_4 \\
Y_4j\sin(k_{4z}h_4) & \cos(k_{4z}h_4)
\end{bmatrix}
\begin{bmatrix}
E_{3z} \\
H_{3z}
\end{bmatrix}
= M_3
\begin{bmatrix}
E_{3z} \\
H_{3z}
\end{bmatrix}
\]

(14)

Substituting Equation (14) into Equation (13) one finds:

\[
\begin{bmatrix}
E_{1z} \\
H_{1z}
\end{bmatrix}
= M_2M_3
\begin{bmatrix}
E_{3z} \\
H_{3z}
\end{bmatrix}
\]

(15)

By applying this method repeatedly for a stratified system of N thin homogeneous thin films we can write:

\[
\begin{bmatrix}
E_{1z} \\
H_{1z}
\end{bmatrix}
= M_2M_3...M_N
\begin{bmatrix}
E_{Nz} \\
E_{Nz}
\end{bmatrix}
\]

(16)

where \( Y_l = \sqrt{\frac{\varepsilon}{\mu_0}} n_l \cos \theta_l \), \( k_l = \frac{2\pi}{A} n_l \) and \( h_l = d_l \cos \theta_l \) for interfaces \( l = 2, 3, ..., N \). (Born & Wolf, 1980) show that the reflection and transmission coefficient amplitudes for a system of N-1 layers (\( l = 2 \) to N) lying on a substrate of refractive index \( n_s \) can be expressed from the matrix entries of the system matrix M as:

\[
R_l = \frac{E_{l1}}{E_{l1}} Y_l m_{11} + Y_l Y_m m_{12} - m_{21} - Y_l m_{22}
\]

\[
T_l = \frac{E_{l1}}{E_{l1}} Y_l Y_m m_{12} + Y_l Y_s m_{12} + m_{21} + Y_l m_{22}
\]

(17)
where $r_\perp$ is referred to as the reflection coefficient for the TE wave. Admittances $Y_1$ and $Y_s$ for the incident medium and the substrate hosting the system of N-1 homogeneous thin films are given by:

$$Y_1 = \sqrt{\frac{\varepsilon_s}{\mu_s} n_1 \cos \theta_1}$$  

(18)

and

$$Y_s = \sqrt{\frac{\varepsilon_s}{\mu_s} n_s \cos \theta_N}$$  

(19)

For the case where the H-field is perpendicular to the plane of incidence (TM wave), the impedances $Y_1, Y_l$ and $Y_s$ must be replaced by $Z_1, Z_l$ and $Z_s$, which are given by

$$Z_1 = \sqrt{\frac{\mu_o \cos \theta_1}{\varepsilon_o n_1}}$$  

(20)

$$Z_l = \sqrt{\frac{\mu_o \cos \theta_l}{\varepsilon_o n_l}} \quad \text{for} \ l = 2, 3, \ldots, N-1$$  

(21)

and

$$Z_s = \sqrt{\frac{\mu_o \cos \theta_N}{\varepsilon_o n_s}}$$  

(22)

1.2 Examples with dielectrics and metal thin films with some experimental results

Expressions derived in the previous section can be applied to find the reflectance curve of thin dielectric or metal films. They can be applied to fit experimental reflectivity data points to determine refractive indices of a dielectric film or metal film relative permittivity and even their thickness. Before we illustrate how it is used, let us apply Equation (17) for the simple case of Fresnel reflection coefficient amplitude for an interface between two semi-infinite media.

1.2.1 Interface between two semi-infinite media (Fresnel reflection coefficient)

This situation can be mimicked by setting $d_2 = 0$ into Equation (13). In other words, interfaces 1 and 2 in Figure 1 collapse into one single interface separating two semi-infinite media of refractive index $n_1$ and $n_2$.

Characteristic matrix in Equation (13) can be used to find the matrix system for two semi-infinite media. Setting for $d_2 = 0$, the matrix system for the two semi-infinite media becomes the identity matrix as $h_2$ equals 0. This means that $m_{11} = m_{22} = 1$ and $m_{12} = m_{21} = 0$.

Substituting the matrix entries into Equation (17) one obtains:

$$r_\perp = \frac{Y_1 - Y_s}{Y_1 + Y_s} = \frac{n_1 \cos \theta_1 - n_2 \cos \theta_2}{n_1 \cos \theta_1 + n_2 \cos \theta_2}$$  

(23)
In the previous equation we use \( n_s = n_2 \) and \( \theta_N = \theta_2 \) for this single interface system. For the TM wave, it can be shown that:

\[
\eta_1 = \frac{Z_1 - Z_e}{Z_1 + Z_e} = \frac{n_2 \cos \theta_1 - n_1 \cos \theta_2}{n_2 \cos \theta_1 + n_1 \cos \theta_2}
\]

(24)

We then retrieve the results for the Fresnel reflection coefficients. Results for the transmission coefficient amplitude (\( t \)) can be obtained in the same manner.

### 1.2.2 Reflectance curve for a thin metallic film of silver or gold (surface plasmons)

A matrix approach is used to compute the reflectance of a thin film coupled to the hypotenuse of a right angle prism. The system shown in Figure 2 can be modeled by using three characteristic matrices for the matching fluid, the glass slide, the metal film and then accounting for the various Fresnel reflection losses at both the entrance and output face of the prism.

![Fig. 2. Path of a laser beam propagating through all interfaces bounded by two given media.](https://www.intechopen.com)

For a one way trip the media are (1) air, (2) glass, (3) matching fluid (greatly exaggerated), (4) glass (slide), (5) metal film (Au or Ag) and (6) air.

(Lévesque, 2011) expressed the characteristic matrix \( M \) of the sub-system of three layers in Figure 2 as

\[
M = M_3 M_4 M_5
\]

(25)

where \( M_3, M_4 \) and \( M_5 \) are the characteristic matrices for the index matching fluid layer, the glass slide and the metal thin film, respectively. Each of these matrices is given by

\[
M_i = \begin{bmatrix}
\cos(\beta_i) & \frac{i}{q_i} \sin(\beta_i) \\
-i q_i \sin(\beta_i) & \cos(\beta_i)
\end{bmatrix}
\]

(26)

where \( i = 3, 4 \) or 5, \( \beta_i \) and \( q_i \) for p-polarized light are expressed as

\[
\beta_i = \frac{2 \pi}{\lambda} n_i d_i \cos \theta_i
\]

(27)
\[ q_i = \sqrt{\frac{\mu_i}{\varepsilon_0}} \frac{1}{\varepsilon_i} \cos \theta_i = \sqrt{\frac{\mu_i}{\varepsilon_0}} q_i' \]  

(28)

respectively, where \( \varepsilon_i (= n_i^2) \) is the relative permittivity of the material. Using Snell’s law, note that

\[ \cos \theta = \left( 1 - \frac{\varepsilon_2 \sin^2 \theta_2}{\varepsilon_i} \right)^{1/2} \]  

(29)

We are assuming all media to be non-magnetic and \( d_3, d_4 \) and \( d_5 \) are the thicknesses of the matching fluid, glass slide and the metal film, respectively. \( \varepsilon_3, \varepsilon_4 \) and \( \varepsilon_5 (= \varepsilon_5' + i \varepsilon_5'') \) are the relative permittivity for the matching fluid, the glass slide and the metal film, respectively. \( \varepsilon_3' \) and \( \varepsilon_5'' \) are respectively, the real and imaginary parts of the metal film relative permittivity. By taking into account the Fresnel reflection losses \( F_1 \) at the input and output faces of the glass prism, the reflectance for the p-polarized light \( R_{Det} \) is given by:

\[ R_{Det} = F_1 \left[ \frac{(m_{11} + m_{12} q_3') q_1' - (m_{21} + m_{22} q_3')}{(m_{11} + m_{12} q_3') q_1' + (m_{21} + m_{22} q_3')} \right]^2 \]  

(30)

where \( m_{ij} \) are the entries of matrix \( M \) and \( F_1 \) is given by

\[ F_1 = \left[ \frac{4n_2 \cos \theta_1 \cos \theta_2}{(\cos \theta_2 + n_2 \cos \theta_1)^2} \right]^2 \]  

(31)

In previous equation \( n_2 \) is the refractive index of the prism. Investigations on optical reflectivity were done on glass slides which were sputtered with gold or silver. These glass slides were pressed against a right angle prism long face and a physical contact was then established with a refractive index matching fluid. The prism is positioned on a rotary stage and a detector is measuring the signal of the reflected beam after minute prism rotations of roughly 0.03º. The p-polarized light at \( \lambda = 632.8 \) nm is incident from one side of a glass prism and reflects upon thin metal films as shown in figure 3. As \( \exp (-j\omega t) \) was assumed in previous sections, all complex permittivity \( \varepsilon \) must be expressed as \( \varepsilon = \varepsilon' + j\varepsilon'' \).

Fig. 3. Experimental set-up to obtain reflectivity data points.
If no film is coating the glass slide, a very sharp increase in reflectivity is expected when $\theta_4$ approaches the critical angle. This sudden increase would occur at $\theta_c = \sin^{-1}(1/n_2) \approx 41.3^\circ$. The main feature of the sharp increase in the reflectivity curve is still obvious in the case of a metalized film. This is so as the penetration of the evanescent field is large enough to feel the presence of air bounding the thin metal film. As silver or gold relative permittivity (optical constant) is complex, $\cos \theta_5$ becomes complex in general and as a result $\theta_5$ is not represented in Fig. 2. This means physically that the field penetrates into the metal film and decays exponentially through the film thickness. At an optimum thickness, the evanescent field excites charge oscillations collectively at the metal-film-air surface (c.f.fig.2), which is often used to probe the metal surface. This phenomenon known as Surface Plasmon Resonance (Raether, 1988; Robertson & Fullerton, 1989; Welford, 1991) is occurring at an angle of $\theta_2$ that is a few degrees greater than $\theta_c$. For a He-Ne laser beam at $\lambda = 632.8$ nm, that is incident from the prism’s side (c.f.fig.2) and then reflecting on silver or gold metal films, surface plasmons (SP) are excited at $\theta_2$ near 43º and 44º, respectively. At these angles, the incident light wave vector matches that of the SP wave vector. At this matching condition, the incident energy delivered by the laser beam excites SP and as a result of energy conservation the reflected beam reaches a very low value. At an optimal thickness, the reflectance curve displays a very sharp reflectivity dip. Figure 4 shows the sudden increase at the critical angle followed by a sharp dip in the reflectance curve in the case of a gold film of various thicknesses, which is overlaying the glass slide.

![Fig. 4. Reflectance curves for gold films of various thicknesses $d_5$ obtained from Eq.(30). We used $d_3 = 10000$ nm and $d_4 = 1000000$ nm (1mm), $n_2 = 1.515$, $n_3 = 1.51$, $n_4 = 1.515$ and $\varepsilon_5 = -11.3+3j$.](image-url)

Reflectance curves for gold films sputtered on glass slides show a sudden rise at the critical angle $\theta_c$ followed by a sharp drop reaching a minimum near 44º. For all film thicknesses, a sudden rise occurs at the critical angle. Note that the reflectance curve for a bare glass slide
(d₅ = 0 nm) is also shown in figure 4. At smaller thicknesses, the electromagnetic field is less confined within the metallic film and does penetrate much more into the air. The penetration depth of the electromagnetic field just before reaching the critical angle (θ < 41.3°) is indicated by a lower reflectance as d₅ gets closer to zero, as shown in Fig.4. The reflectivity drop beyond θc is known as Surface Plasmon Resonance (SPR). SPR is discussed extensively in the literature and is also used in many applications. Good fitting of both regions displaying large optical intensity change is also useful in chemical sensing devices. As a result fitting of both regions is attempted using the exact function curve without any approximations given by Eq. (30). Eq. (30) is only valid for incident plane wave. Therefore, the reflectivity data points were obtained for a very well-collimated incident laser beam. A beam that is slightly converging would cause more discrepancy between the curve produced from Eq. (30) and the reflectivity data points. Although the Fresnel loss at the transparent matching fluid-glass slide interface is very small, it was taken into account in Eq. (30), using d₃=10 000nm (10 µm) in matrix M₃. The theoretical reflectance curve is not affected much by the matching fluid thickness d₃. It was found that d₃ exceeding 50 µm produces larger oscillations in the reflectance curve predicted by Eq.(30). As the oscillations are not noticeable amongst the experimental data points, the value of d₃ = 10 µm was deemed to be reasonable. A function curve from Eq. (30) is generated by changing three output parameters ε₅', ε₅'' and d₅. The sum of the squared differences (SSQ) between RDET and the experimental data points Ri is calculated. The best fit is determined when the SSQ is reaching a minimum. The SSQ is defined as:

$$SSQ = \sum_{i=1}^{N} (R_i - R_{DET})^2$$

(32)

where i is a subscript for each of the N data points from the data acquisition. Each sample was placed on a rotary stage as shown in Figure 3 and a moving Si-pin diode is rotating to track down the reflected beam to measure a DC signal as a function of θ₂. The reflectivity data points and typical fits are shown in Figure 5.

In the fit in Fig. 5a, we used n₂ =n₄ = 1.515, n₃ = 1.47(glycerol) for red light, d₃ = 10 000 nm, ε₅ = -11.55+3.132j and d₅ =43.34 nm.

In the fit in Fig. 5b, we used n₂ =n₄ = 1.515, n₃ = 1.47(glycerol) for red light, d₃ = 10 000 nm, ε₅ ' = -10.38+2.22j and d₅ = 53.8 nm. The three output parameters (ε₅', ε₅'' and d₅) minimizing the SSQ determine the best fit. Plotting the SSQ in 3D as a function of ε₅'' and d₅ at ε₅' = 3.132 shows there is indeed a minimum in the SSQ for the fit shown in Fig.5a. Figure 6 shows a 3D plot of the SSQ near the output parameters that produced (Lévesque, 2011) the best fit in Fig. 5a. 3D plots at values slightly different from ε₅'' = 3.132 yield larger values for the minimum.

2. Wave propagation in a dielectric waveguide

In this section, we apply the matrix formalism to a dielectric waveguide. We will describe how the reflectance curve changes for a system such as the one depicted in Fig. 2 if a dielectric film is overlaying the metal film. It will be shown that waveguide modes can be excited in a dielectric thin film overlaying a metal such as silver or gold and that waveguide modes supported by the dielectric film depend upon its thickness.
Fig. 5. Reflectivity data points (+) and a fit (solid line) produced from Eq.(30) for two different gold films.

Fig. 6. 3D plot of SSQ as a function of two output parameters at a given value of $\varepsilon_5'' (= 3.132)$. We assumed the glycerol layer ($d_5$) to be 10 µm and the thickness of the glass slide is 1 mm ($d_4$). The SSQ reaches a minimum of 0.01298 for $\varepsilon_5' = -11.55$, $\varepsilon_5'' = 3.132$ and $d_5 = 43.34$ nm.
2.1 Wave propagation in dielectric films

Let us consider a dielectric film of thickness $d_6$ overlaying the metal film in Figure 2. We will be assuming that the top surface of the overlaying dielectric is bounded by the semi-infinite air medium. The characteristic matrix $M$ for the sub-system of four layers can be expressed as:

$$M = M_3 M_4 M_5 M_6$$  \hfill (33)

where $M_3$, $M_4$, $M_5$ and $M_6$ are the characteristic matrices for the index matching fluid layer, the glass slide, the metal thin film and the thin dielectric film, respectively. Each matrix in Eq.(33) is given by Eq.(26) for $i = 3,4,5$ and 6 and the reflectance for the p-polarized wave is given by Eq.(30). For this four layer system, $q'_6$ in Eq.(30) should be replaced by $q'_7$ (air) and $m_{11}$, $m_{12}$, $m_{21}$ and $m_{22}$ are the entries of the system matrix given by Eq.(33). The expression for $q'_6$ is given by Eq.(28) and is used in the computation of $M_6$ for the dielectric film characteristic matrix.

2.1.1 Computation of reflectance with a thin dielectric film and experimental results

Eq. (30) can be used with the minor modifications discussed in section 2.1 to find the reflectance of the system in Fig. 2 with an extra dielectric film processed on the metal film. The dielectric film can support waveguide modes if the laser beam is directed at very precise incident angle $\theta$. Let us consider a transparent polymer film with a real permittivity $\varepsilon_6 = 2.30$ processed on a silver film. The computation is done for a silver film that is 50 nm thick. Silver permittivity is assumed to be $\varepsilon_5 = -18.0 +0.6i$ and the prism refractive index to be 2.15 ($\text{ZrO}_2$) for He-Ne laser at $\lambda = 632.8$ nm. We also assume that the metal film is directly coated on the prism long face and as a result we set $d_3 = d_4 = 0$. In other words $M_3$ and $M_4$ are expressed by identity matrices. Figure 7 is showing the reflectance curve for a dielectric film of different thickness that is overlaying the silver film coated on the high refractive index ZrO$_2$ prism.

![Fig. 7](image-url)

Fig. 7. a) Reflectance curve for a lossless dielectric film of 1.7 μm overlaying a thin silver film
b) Reflectance curve for a lossless dielectric film of 2.5 μm overlaying a thin silver film
In figure 7a, a series of very sharp reflectivity drops occur in the reflectance curve for $\theta_2$ within the range 35º-45º. These sharp reflectivity drops with small full width at half maximum (FWHM) are waveguide modes supported by the dielectric film. The last reflectivity dip with a larger FWHM near $\theta_2 \sim 50º$ is due to surface plasmon resonance (SPR) and is mostly depending upon the metal film properties and its thickness as discussed in section 1.2.2. A thicker dielectric film (c.f. fig. 7b) can support more waveguide modes and as a result the number of sharp reflectivity dip for $\theta_2$ within the range 35º to 45º is expected to be greater. Note that the FWHM of the SPR dip remains at the same position as the metal film thickness was not changed. These waveguide modes do not propagate a very large distance as light is slightly attenuated when reflecting at the metal-dielectric film interface. Therefore, at precise angle $\theta_2$ the incident light is probing the dielectric film locally before being reflected by the thin metal film. Nevertheless, the laser beam is simultaneously probing the metal and the dielectric films because it creates SPR on the thin metal film and waveguide modes are being supported by the dielectric film. In practice, dielectric films are not lossless (Podgorsek & Franke, 2002) and their permittivity should be expressed using a small imaginary part. Let us assume that each dielectric films in Fig. 7 have a permittivity of $\varepsilon_6 = 2.30 + 0.005j$.

![Reflectance curve for a dielectric film](https://www.intechopen.com)

**Fig. 8.** a) Reflectance curve for a dielectric film ($\varepsilon_6 = 2.30 + 0.005j$, $d_6 = 1.7 \mu m$) overlaying the metal film. b) Reflectance curve for a dielectric film ($\varepsilon_6 = 2.30 + 0.005j$, $d_6 = 2.5 \mu m$) overlaying the metal film.

Note from figures 7 and 8 that the waveguide mode dips are greatly attenuated when a small imaginary part is assumed in the dielectric film permittivity. The dips at larger angles (near 45º) are getting smaller as the propagation distance into in the dielectric film is larger as $\theta_2$ increases. Note that the SPR dip is not much affected by the imaginary part of $\varepsilon_6$. Essentially, the whole 4-layer system of prism material-silver film- dielectric film-air can be mounted on a rotary stage and the angle $\theta_2$ can be varied using a set-up similar to that
shown in figure 3. As it is difficult to obtain a large dynamic range in the measurements of reflectivity data points, scans must be done successively to cover a long range of incident angle. Figure 9 shows reflectance curves for a transparent layer of polyimide processed directly on silver films. Ranges of incident angle $\theta_2$ where no noticeable change in reflectivity were observed are not shown. Only the dips in the reflectivity data points are fitted by Eq. (30).

Fig. 9. Reflectivity data points of the 4-layer system and fits (solid lines) from Eq. (30) for
a) ZrO$_2$ prism-Ag-polyimide film   b) glass prism-Ag-polyimide film

Using a method based on the optimization of the sum of square (SSQ) as presented in section 1.2.2, thicknesses and the complex permittivities of both films can be estimated. Values obtained from the minimization of the SSQ are given in table 1. Uncertainties are estimated from a method described by (Lévesque et al., 1994).

3. Diffraction efficiency (DE) in dielectric periodic grating structures

Abrupt changes in reflectivity or transmission were first observed in gratings as early as 1902 (Wood, 1902). These so-called anomalies in diffraction efficiency (DE) occurring over an angle range or a wavelength spectrum are very different from the normally smooth diffraction curves. These abrupt changes in DE led researchers to design and investigate resonant filters for applications in many devices including gratings.

Rigorous coupled wave analysis (RCWA) has been used extensively (Moharam et al., 1995; Lalanne & Morris, 1996; Lenaerts et al., 2005) to calculate diffraction efficiencies (DE) in waveguide structures. The application of RCWA to resonant-grating systems has been
investigated mostly for both the TE and TM polarization. In this section, the basic binary dielectric rectangular-groove grating is treated with careful considerations on the computation of DE. The results obtained for binary dielectric rectangular-groove grating are also applied to metallic grating. Introduction to photonic bandgap systems are discussed and some examples are presented at the end of this section.

3.1 Theory of coupled wave analysis
As the numerical RCWA method is introduced extensively in the literature, only the basics equations will be presented in this section. Computation will be done for the TM wave on ridge binary grating bounded by two semi-infinite dielectric media of real permittivities \(\varepsilon_1\) and \(\varepsilon_3\). The type of structures presented in this section is depicted in figure 10.

![Fig. 10. Basic structure of the binary rectangular-groove grating bounded by two semi-infinite dielectrics.](image)

The relative permittivity \(\varepsilon(x)\) of the modulated region shown in figure 10 is varying periodically along the \(x\)-direction and is defined as:

\[
\varepsilon(x) = \sum_s \varepsilon_s \exp(-2\pi j s x / \Lambda)
\]  
(34)

where \(\varepsilon_s\) is the \(s\)th Fourier component of the relative permittivity in the grating region \((0 < z < h)\), which can be complex in the case of metallic gratings. The incident normalized magnetic field that is normal to the plane of incidence (cf. fig. 10) is given by:

\[
H_{inc,y} = \exp[-j\kappa n y (\sin \theta x + \cos \theta z)]
\]  
(35)

where \(\kappa = 2\pi / \lambda\). \(\theta\) is the incident angle with respect to the \(z\)-axis as shown in figure 10.

The normalized solutions in regions 1 \((z < 0)\) and 3 \((z > h)\) are expressed as:

\[
H_{1,y} = H_{inc,y} + \sum_i R_i \exp[-j(k_{1,i} x - k_{1,i,z} z)]
\]  
(36)

\[
H_{3,y} = \sum_i T_i \exp[-j(k_{3,i} x + k_{3,i,z}(z - h))]
\]  
(37)
where \( k_{xi} \) is defined by the Floquet condition, i.e.,

\[
 k_{xi} = k_i (n_1 \sin \theta_i - i (\lambda / \Lambda))
\]

(38).

In previous equations, \( \Lambda \) is the grating spacing, \( n_1 (= \sqrt{\varepsilon_1}) \) is the refractive index of medium 1 and

\[
 k_{l,zi} = \begin{cases} 
 k_{o} \left[ \left( n_2^2 - \left( \frac{k_{zi}}{k_{o}} \right)^2 \right)^{1/2} \right] & \text{for } k_{zi} > k_{o} n_1 \\
 -jk_{o} \left[ \left( \frac{k_{zi}}{k_{o}} \right)^2 - n_1^2 \right]^{1/2} & \text{for } k_{zi} > k_{o} n_1 
\end{cases}
\]

(39)

with \( l = 1,3 \), \( n_3 (= \sqrt{\varepsilon_3}) \) is the refractive index of medium 3.

\( R_i \) and \( T_i \) are the normalized electric-field amplitudes of the \( i \)th diffracted wave in media 1 and 3, respectively. In the grating region \((0 < z < h)\) the tangential magnetic \((y\text{-component})\) and electric \((x\text{-component})\) fields of the TM wave may be expressed as a Fourier expansion:

\[
 H_y = \sum_i \bar{U}_y(z) \exp(-jk_{zi}x)
\]

\[
 E_x = j\left( \frac{\mu_0}{\varepsilon_0} \right)^{1/2} \sum_i \bar{S}_x(z) \exp(-jk_{zi}x)
\]

(40)

where \( \bar{U}_y(z) \) and \( \bar{S}_x(z) \) are the normalized amplitudes of the \( i \)th space-harmonic which satisfy Maxwell’s equations, i.e.,

\[
 \frac{\partial E_x}{\partial z} = -j \omega \mu_0 H_y + \frac{\partial E_y}{\partial x},
\]

\[
 \frac{1}{\varepsilon(x)} \frac{\partial H_y}{\partial x} = j \omega \varepsilon_0 E_z
\]

(41)

where a temporal dependence of \( \exp \left( j \omega t \right) \) is assumed \((i^2 = -1)\) and \( \omega \) is the angular optical frequency. \( \varepsilon_0 \) and \( \mu_0 \) are respectively the permittivity and permeability of free space. As the \( \exp \left( j \omega t \right) \) is used, all complex permittivity must be expressed under \( \varepsilon = \varepsilon' - j \varepsilon'' \).

Substituting the set of equations (40) into Maxwell’s equations and eliminating \( E_z \), the coupled-wave equations can be expressed in the matrix form as:

\[
 \begin{bmatrix} \frac{\partial \bar{U}_y}{\partial z'} \ \\ \frac{\partial \bar{S}_x}{\partial z'} \end{bmatrix} = \begin{bmatrix} 0 & E \\ B & 0 \end{bmatrix} \begin{bmatrix} \bar{U}_y \\ \bar{S}_x \end{bmatrix}
\]

(42)

where \( z' \) equals \( k_{zi} \).

Previous equations under the matrix form can be reduced to

\[
 \begin{bmatrix} \frac{\partial^2 \bar{U}_y}{\partial z'^2} \end{bmatrix} = [EB] \begin{bmatrix} \bar{U}_y \end{bmatrix}
\]

(43)
where \( B = K_x E^{-1} K_x - I \). \( E \) is the matrix formed by the permittivity elements, \( K_x \) is a diagonal matrix, with their diagonal entries being equal to \( k_m / k_o \) and \( I \) is the identity matrix. The solutions of Eq. (43) and the set of Eq. (42) for the space harmonics of the tangential magnetic and electric fields in the grating region are expressed as:

\[
U_{m}(z) = \sum_{m=1}^{n} w_{j,m}(c_{m}^{+} \exp[-jk_0 q_m z] + c_{m}^{-} \exp[+jk_0 q_m (z-h)])
\]

\[
S_{m}(z) = \sum_{m=1}^{n} v_{i,m}(-c_{m}^{+} \exp[-jk_0 q_m z] + c_{m}^{+} \exp[+jk_0 q_m (z-h)])
\]

where, \( w_{j,m} \) and \( q_m \) are the elements of the eigenvector matrix \( W \) and the positive square root of the eigenvalues of matrix \( G (=-EB) \), respectively. The quantities \( c_{m}^{+} \) and \( c_{m}^{-} \) are unknown constants (vectors) to be determined from the boundary conditions. The amplitudes of the diffracted fields \( R_i \) and \( T_i \) are calculated by matching the tangential electric and magnetic field components at the two boundaries. Using Eqs. (35), (36), (44) and the previously defined matrices, the boundary conditions at the input boundary \((z = 0)\) are:

\[
\delta_{i,0} + R_i = Wc^+ + WXc^-
\]

and

\[
\frac{j \cos \theta}{n_1} \delta_{i,0} - jZ_1 R_i = Vc^+ - VXc^-
\]

where \( X \) and \( Z_1 \) are diagonal matrices with diagonal elements \( \exp(-jk_0 q_m h) \) and \( k_1 z_i / (n_1^2 k_0) \), respectively. \( c^+ \) and \( c^- \) are vectors of the diffracted amplitude in the \( i \)th order. From (42) and (44), it can be shown that

\[
V = jE^{-1}WQ
\]

where \( v_{m,i} \) are the elements of the product matrix with \( Q \) being a diagonal matrix with diagonal entries \( q_i \).

At \( z = h \), the boundary conditions are:

\[
WXc^+ + WXc^- = T_i
\]

and

\[
VXc^+ - VXc^- = jZ_3 T_i
\]

where \( Z_3 \) is the diagonal matrix with diagonal elements \( k_3 z_i / (n_3^2 k_0) \). Multiplying each member of Eq. (48) by \(-jZ_3\) and using Eq. (49) to eliminate \( T_i \) vectors \( c \) and \( c^+ \) are related by:

\[
c^- = (jZ_3 W + V)^{-1} (-jZ_3 W + V) X c^+
\]

Multiplying each member of Eq. (45) by \( jZ_1 \) and using Eq. (46) to eliminate \( R_i \) a numerical computation can be found for \( c^+ \) by making use of Eq. (50), that is:
where

\[
C = [(jZ_1 W + V) + (jZ_1 W - V)X(jZ_3 W + V)^{-1}(-jZ_3 W + V)X]
\]

Note in Eq. (51) that \( \delta_{i,0} \) is a column vector. In the case of a solution truncated to the first negative and positive orders,

\[
\delta_{i,0} = \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix}
\]

assuming the incident wave to be a plane wave. In this particular case

\[
\frac{j\cos \theta}{n_1} + jZ_1 \delta_{i,0} = \begin{bmatrix} 0 \\ j\cos \theta/n_1 + jZ_1(2,2) \\ 0 \end{bmatrix}
\]

where \( Z_1(2,2) \) is the element on line 2 and column 2 of matrix \( Z \). Finally, the vector on the right-hand side of Eq. (54) is applied to the inverse matrix of \( C \) to find the column vector for the diffracted amplitude \( c^+ \) from Eq. (51). Then \( c^- \) is found from Eq. (50) and the normalized electric field amplitudes for \( R_i \) and \( T_i \) can be found from Eqs. (48) and (49).

Substituting Eq. (34) and Eq. (44) into Maxwell’s equations and eliminating \( E_z \), it can be shown that

\[
\frac{\partial S_{xmn}}{\partial \varepsilon} = j \left( \sum_p \frac{k_{m}}{k_0} e^{-i p} \kappa_{mn} U_{ypr} - U_{ypr} \right)
\]

Eq. (55) is one of the two coupled-wave equations involving the inverse permittivity for the case of TM polarization only. In the conventional formulation (Wang et al., 1990; Magnusson & Wang, 1992; Tibuleac & Magnusson, 1997) the term \( e^{-i p} \) is treated by taking the inverse of the matrix \( E \) defined by the permittivity components (Moharam & Gaylord, 1981), with the \( i, p \) elements being equal to \( \varepsilon_{i,p} \). In the reformulation of the eigenvalue problem (Lalanne & Morris, 1996), the term \( e^{-i p} \) is considered in a different manner by forming a matrix \( A \) of the inverse-permittivity coefficient harmonics for the two regions inside the modulated region. Fourier expansion in Eq. (34) is modified to:

\[
\frac{1}{\varepsilon(x)} = \sum_s \left( \frac{1}{\varepsilon_s} \right) \exp(-2\pi j sx / \Lambda)
\]

where \( (1/\varepsilon) \) is the \( s \)th Fourier component of the relative permittivity in the grating region. Since the coupled-wave equations do not involve the inverse of the permittivity in the coupled-wave equations for the TE wave, matrix \( A \) is not needed in numerical computations.
and the eigenvalue problem is greatly simplified in this case. As a result, solutions for the TE wave are more stable in metallic lamellar gratings.

Only the DE in reflection and transmission for zeroth order are computed in the examples that will be discussed throughout this section. The diffraction efficiencies in both reflection (DE_r) and transmission (DE_t) are defined as:

\[ DE_r = R_0 R_1^* \text{Re} \left( \frac{k_{1,0} \cos \theta_j}{k_1 \cos \theta} \right) \]  \hspace{1cm} (57)

and

\[ DE_t = T_0 T_1^* \text{Re} \left( \frac{k_{3,0} \cos \theta_j}{k_3 \cos \theta} \right) \]  \hspace{1cm} (58)

### 3.1.1 Examples with binary dielectric periodic gratings

Let us consider a binary rectangular-groove grating with real permittivity \( \varepsilon_L \) and \( \varepsilon_H \) as shown in figure 10. In the case of notch filters the higher permittivity value \( \varepsilon_H (\Lambda / 2 < x < \Lambda) \) is greater than \( \varepsilon_L (0 < x < \Lambda / 2) \). Figure 11 shows the numerical computation for DE from the RCWA formulation for the TM wave when only three orders (m = -1, 0, 1) are retained in the computation.

![Fig. 11. DE_r and DE_t for a binary dielectric periodic grating for \( \varepsilon_L = 4.00, \varepsilon_H = 4.41, \Lambda = 314 \) nm, \( n_1 = 1.00 \) (air), \( n_3 = 1.52 \) (glass) and h = 134 nm.](image)

From the principle of energy conservation, the sum of DE_r and DE_t must be equal to unity. This principle is useful to decide if the number of orders retained in the computation is sufficient. As no deviation from unity is seen in the sum of DE_r and DE_t in figure 11, three orders is deemed to be enough to describe the diffraction efficiencies within this narrow wavelength spectrum. At a wavelength of roughly 511.3 nm all the optical energy is reflected back in the opposite direction from that of the incident light. As a result, DE_t is reaching a zero value as destructive interferences occur within the grating at this precise wavelength value of 511.3 nm.

### 3.1.2 Examples with metallic periodic gratings

The theory presented in section 3.1 can be applied to metallic periodic gratings. For the TM wave many terms need to be retained in the calculation to reach convergence (Li &
Electromagnetic Waves

For the sake of saving time, a fairly accurate computation is reached after retaining ten orders when using the reformulated eigenvalue problem (Lalanne & Morris, 1996). Figure 12 shows \( DE_R \) for a metallic periodic grating using a 3D plot. Metallic periodic gratings are used to excite surface plasmons (SP) to improve Surface-enhanced-Raman-Scattering (SERS) sensor performances (Sheng et al., 1982). At a given wavelength \( \lambda \), the reflectivity of the metallic grating should be symmetric with the incident angle \( \theta \). If a reflectivity drop occurs due to SP at \( \theta \), the metallic periodic grating should display a similar drop at \(-\theta\). Note that two minima occur on either side of normal incidence (\( \theta = 0^\circ \)) and one single minimum is displayed at normal incidence for \( \lambda \sim 630 \) nm. Basically each minimum in \( DE_R \) forms two valleys which crisscross at normal incidence and \( \lambda \sim 630 \) nm. This point will become important in the next section where photonic band gap is discussed.

Fig. 12. 3D plot of \( DE_R \) for a periodic metallic grating. In the calculation, we used \( n_1 = 1 \), \( \varepsilon_3 = \varepsilon_2 = -17.75 - 0.7j \), \( \Lambda = 600 nm \), \( \varepsilon_1 = -17.75 - 0.7j \), \( \varepsilon_{11} = 1 \), and \( h = 10.5 \) nm.

3.2 Photonic bandgap in metallic periodic gratings

Resonant surface plasmon (SP) coupling involving metallic periodic gratings has been extensively studied over the past years and more recently in work looking at photonic devices (Park et al., 2003; Barnes et al. 2003; Ebbesen et al., 1998; Ye & Zhang, 2004) surface-enhanced Raman scattering (Sheng et al., 1982) and photonic bandgaps (Barnes et al., 1996). Corrugated surfaces are commonly produced by direct exposure of a photoresist film to a holographic interference pattern. There is some experimental evidence that owing to nonlinear response of the photoresist, this technique leads to the presence of higher harmonics in addition to the fundamental pattern that is inscribed (Gallatin, 1987; Pai & Awada, 1991). The higher harmonics can then influence the propagation of the SP on the metallic periodic grating and, in particular, can generate a bandgap in the plasmon dispersion curve.

3.2.1 Generating a photonic bandgap with two metallic periodic gratings

Let us consider two metallic sinusoidal gratings with vectors \( K_1 (= 2\pi/A_1) \) and \( K_2 (=2\pi/A_2) \) inscribed at the same location on the film surface. One grating acts as a coupler that allows light
to generate SPs while the second grating creates a bandgap in the dispersion curve for the SP propagation. Herein, we consider the case $K_2 = 2K_1$. More complicated cases such as $K_2 < 2K_1$ have also been investigated and may be found in the literature (Lévesque & Rochon, 2005).

The SP dispersion curve for a uniform silver or gold film in the absence of a gap is shown in Figure 13a and is described by:

$$k_{SP} = \frac{\omega}{c} \left( \frac{\epsilon_m \epsilon_d}{\epsilon_m + \epsilon_d} \right)^{1/2}$$

(59)

where $k_{SP}$ is the wave vector of the SP modes coupled at the surface and $\epsilon_m$ and $\epsilon_d$ are the permittivities of the metal and dielectric material (air). The dispersion line for light incident at an angle $\theta$ and scattered by a vector $K_1$ is given by:

$$k_{light} = \frac{\omega}{c} \sin \theta \pm m_1 K_1$$

(60)

Note from Figure 13a that at normal incidence ($\theta = 0^\circ$) SPs will be excited at a single wavelength from a loss or gain of light momentum by the grating Bragg vector $K_1 = 2\pi/\Lambda$. Scattering of incident light from the metallic grating at a given incident angle can fulfill the phase-matching condition ($k_{SP} = k_{light}$) for SP excitation. As $\theta$ increases from zero SPs can be generated if light scatters by a Bragg vector $\pm K_1$, i.e., two valleys will form for $\theta > 0^\circ$ and $\theta < 0^\circ$ as shown in Figure 13b. Experimentally, a fairly sharp dip in the reflectivity curve ($R_p$) was observed for the $p$-polarized light but not for the $s$-polarized light ($R_s$). To emphasize the SP contribution, the $R_p$ reflectance curves were normalized to $R_s$ in the range 600-900 nm spectral range. Curves shown in Figure 13b were predicted by DE computations shown in Figure 12.

The SP dispersion curves for the doubly corrugated surfaces and light lines are shown in Figure 14a.

It can be seen from Figure 14a) that two SPs can be generated at normal incidence as a bandgap is being created by the grating of Bragg vector $K_2$. As a result, SPs can be generated at $\omega = \omega_1$ and $\omega = \omega_2$. This means the band will open as shown in Figure 14b, where two minima are shown in the experimental data points for all incident angles (Lévesque & Rochon, 2005). Each of these minima corresponds to SP excitation at the air-metal grating surface when light is scattered by Bragg vector $\pm K_1$. 

www.intechopen.com
3.2.2 Processing of the single and double metallic corrugated surfaces
Surface corrugations with selected pitches (Bragg vectors) can be produced on azopolymer films by direct exposure of an interference pattern from two coherent light beams at $\lambda = 532$ nm, as shown in Figure 15a. The two desired spacing are obtained by adjusting the angle $\varphi$ (c.f. fig.15a) between the writing beams, and their depth is determined by their exposure time. The films under investigation have two superimposed sinusoidal gratings with vectors $K_1$ and $K_2$. These azopolymer films were prepared on glass slides and then coated with a 50

![Diagram of experimental set-up](image)

Fig. 15. a) Experimental set-up to produce corrugated metallic grating. b) Atomic force microscope image of a double metallic grating. Pitches here are 700 and 375 nm with their respective depths of 19±1 nm and 7.0±0.5 nm.
nm thick gold film by sputter. The surface profile \( s(x) \) shown in the atomic force microscope image in Figure 15b can be represented as

\[
s(x) = h_1 \sin(K_1 x) + h_2 \sin(K_2 x + \phi_2)
\]  

where \( x \) is the spatial coordinate, \( h_1 \) and \( h_2 \) are the amplitudes of the two harmonic components, and \( \phi_2 \) is their relative phase.

4. Conclusion

The matrix formalism was shown to be efficient to predict the reflectance curves of both uniform films and periodic corrugated surfaces. It was shown in this chapter that the reflectance derived from the matrix formalism allows precise determinations of refractive indices and thickness when it is fitted to experimental data points. The principle to determine a good fit from the minimization of the sum of squares was presented in some details. The application of the sum of squares in more complex structures involving transparent overlaying films were also introduced along with waveguide modes. It was also shown that the matrix formalism can be used in numerical techniques and can be applied to periodic gratings to predict diffraction efficiencies. Systems of metallic periodic gratings were discussed and it was shown that photonic bandgap can be produced by superposition of two inscribed corrugated surface on an azopolymer film. The modulated films were made by holographic technique to write surface relief structures. One grating is written to have a spacing vector \( K_2 \) to generate a bandgap in the SP dispersion curve. A second grating with grating spacing vector \( K_1 \) is superimposed and allows the coupling of the incident light to generate the SP itself.

5. References

This book is dedicated to various aspects of electromagnetic wave theory and its applications in science and technology. The covered topics include the fundamental physics of electromagnetic waves, theory of electromagnetic wave propagation and scattering, methods of computational analysis, material characterization, electromagnetic properties of plasma, analysis and applications of periodic structures and waveguide components, and finally, the biological effects and medical applications of electromagnetic fields.
