Synthesis, Characterization and Properties of Zirconium Oxide (ZrO$_2$)-Doped Titanium Oxide (TiO$_2$) Thin Films Obtained via Sol-Gel Process

Rabah Bensaha and Hanene Bensouyad

Additional information is available at the end of the chapter

http://dx.doi.org/10.5772/51155

1. Introduction

Sol–gel process [1-3] is an attractive alternative to other methods for synthesis of ceramics and glasses for many reasons: for example, low temperature synthesis, simple equipment’s to be used, thin film formability and so on. Particularly, sol–gel process is very useful for thin film deposition because of the capability to coat materials of various shapes and/or large area, to control the composition easily for obtaining solutions of homogeneity and controlled concentration without using expensive equipment.

Historically, metal alkoxides have been employed in sol–gel process, which readily undergo catalyzed hydrolysis and condensation to form nanoscale oxide or hydroxide particles. Still in general, metal alkoxides are often used as raw materials in sol–gel process, but many of the alkoxides are very difficult to be obtained because of the high sensitivity to the atmospheric moisture [4-9]. In ordinary sol–gel processing, starting compositions as well as reaction conditions are selected so as to maintain the mixture in a homogeneous state throughout the processes including mixing of starting compounds, gelation, aging, drying and heat-treatment.

Titanium and zirconium oxides are very promising candidates for future technology of thin layers because of their interesting mechanical, thermal and chemical properties. Titanium oxide (TiO$_2$) is a cheap, non-toxic, and non-biodegradable material, besides their widely uses in various industries [10]. Moreover, it is a semiconductor under the form of thin films. Its insensitivity to visible light due to its band gap (3.2 eV) enables it to absorb in the near ultraviolet region [11], even though its low efficiency. Hence, it can be sensitized by a great number of dyes; some of them allow a conversion rate incident photon–electron approaching unity. Thus, these various applications arouse great interest in the study of
titanium oxide thin films. The significant uses of TiO$_2$ thin films are in solar cells [12], photocatalytic [13] and electro-chromic systems [14], in other words, they are mainly found their use in optics.

TiO$_2$ thin films are extensively studied because of their interesting chemical, electrical and optical properties [15,16]. TiO$_2$: film in anatase phase could accomplish the photocatalytic degradation of organic compounds under the radiation of UV. So, it has a variety of application prospects in the field of environmental protection [17,18]. TiO$_2$: thin film in rutile phase is known as a good blood compatibility material and can be used as artificial heart valves [19]. In addition, TiO$_2$: films are important optical films due to their high reflective index and transparency over a wide spectral range [16].

During the two last decades, several methods have been used for the TiO$_2$: thin films preparation, such as chemical vapor deposition [20], chemical spray pyrolysis [21], pulsed laser deposition [22] and sol–gel method [23]. In comparison with other methods, the sol–gel method has some advantages such as controllability, reliability, reproducibility and can be selected for the preparation of nano-structured thin films [23,24]. Sol–gel coating has been classified as two different methods such as dip and spin coating.

The dip-coating has considerably been used for preparation TiO$_2$: nanostructured thin films [25–27]. Experimental results have shown that the preparation of high transparent TiO$_2$: thin film by dip-coating method needs to control morphology, thickness of the film and the anatase-brookite-rutile phase transformation [26,28].

Additions of another semiconductor have been used to improve the properties of titanium dioxide. In principle, the coupling of different semiconductor oxides seems useful in order to achieve a higher photocatalytic activity [29]. Various composites formed by TiO$_2$: and other inorganic oxides such as SiO$_2$: [30], ZrO$_2$: [31] SnO$_2$: [32], CuO [33], MgO [34], WO$_3$: [35], In$_2$O$_3$: [36], ZnO [37], MoO$_3$: [38], PbS [39], and so on, have been reported. Zirconium oxide (ZrO$_2$) has good dielectric and optical properties [41,42] it has a high refraction index [43]. Additionally, it has a very good transparency on a broad spectral field [44], a great chemical stability and a threshold of resistance to high laser flow. All these properties led to miscellaneous applications such as optical filters, laser mirrors [45] or barriers layers from the heat [46]. ZrO$_2$: films are also employed as plug layer for superconducting ceramics [47,48], like biomaterial for prostheses [49,50], as gas sensor [51] or like component in combustible batteries [52]. Basically, ZrO$_2$: itself is an insulating direct wide gap metal oxide, with an optical band gap in the range 5.0-5.85 eV [53].

The aim of the present work is to investigate the transformation behaviors and the effect; of a smaller ratio range of ZrO$_2$: doping on the surface area of TiO$_2$: thin films, light absorption, band gap energy, variations of crystal granularity, phase composition and especially on the evolution of the crystallite size and defects concentration with annealing treatments (heat treatments) and layers thickness of the samples produced. So that in this chapter, we report the study of structural, thermal and optical properties of ZrO$_2$:doped TiO$_2$: thin films deposited by the sol–gel process. Several experimental techniques were used to characterize
Synthesis, Characterization and Properties of Zirconium Oxide (ZrO\textsubscript{2})-Doped Titanium Oxide (TiO\textsubscript{2}) Thin Films Obtained via Sol-Gel Process

2. Experiments

Our 5\% ZrO\textsubscript{2}-doped TiO\textsubscript{2} thin films were prepared by dip coating, in three steps. The first step: the dissolution of 1 mol of butanol (C\textsubscript{4}H\textsubscript{9}OH) as solvent, 4 mol of acetic acid (C\textsubscript{2}H\textsubscript{4}O\textsubscript{2}), 1 mol of distilled water and 1 mol of tetrabutylorthotitanate (C\textsubscript{4}H\textsubscript{9}O)\textsubscript{4}Ti. In the second step, the solution of ZrO\textsubscript{2} was prepared from the dissolution of 1 mol of zirconium oxychloride salt (ZrOCl\textsubscript{2}•8H\textsubscript{2}O) in distilled water and 2 mol of ethanol (95\%) as catalyst. Finally, the solution of TiO\textsubscript{2} was doped with ZrO\textsubscript{2}. Then, the resultant yellowish transparent solutions were ready for use. The substrates were dip-coated in the solutions at a constant rate of 6.25 cm.s\textsuperscript{-1}. After each dipping, thin films were dried for 30 min at a distance of 40 cm from a 500 W light source. The drying temperature of the light source is approximately equal to 100 °C. Subsequently, thin films were heat treated in the temperature range 350–450 °C, with a temperature increase rate of 5°C.min\textsuperscript{-1}, for 2 h in the furnace. The powders obtained from the xerogel were prepared in room temperature and under air atmosphere.

After each dipping, the thin films were dried for 30 min, at a distance of 40 cm from a 500 Wight source. The drying temperature of the light source is approximately equal to 100 °C. Subsequently, thin films were heat treated in the temperature range 350–450 °C, with a temperature increase rate of 5 °C min\textsuperscript{-1}, for 2 h in the furnace. The powders obtained from the xerogel were prepared with an annealing till three months in room temperature and under air atmosphere.

To investigate the transformation behaviors and the effect; of a smaller ratio range of ZrO\textsubscript{2}; doping on the surface area of TiO\textsubscript{2}; thin films, light absorption, band gap energy, variations of crystal granularity, phase composition and especially on the evolution of the crystallite size and defects concentration with annealing treatments (heat treatments) and layers thickness of the samples produced.

So that in this chapter, we report the study of structural, thermal and optical properties of ZrO\textsubscript{2}-doped TiO\textsubscript{2} thin films deposited by the sol–gel process.

Several experimental techniques were used to characterize structural and optical properties resulting from different annealing treatments and different layer thicknesses: X-ray powder diffraction, Fourier transforms infrared (FTIR), Raman spectroscopy, Scanning electron microscopy (SEM), differential scanning calorimetric (DSC), Scanning electron microscopy (SEM), the energy dispersive X-ray spectrometry (EDX) and UV spectroscopy.

To obtain nanomaterial’s with controlled properties, it is most often involves the use of mineral additives (dyes, semiconductors, metal particles, rare earth, etc.) in small quantities. These additions can promote densification or control the phenomenon of grain growth, or to change the structural, physical and optical properties. So the presence of impurities in a matrix can stabilize, improve or modify the various properties of a material. Generally, thin layers of doped TiO\textsubscript{2} give hope of significant performance gains and new applications.
and films diffraction, Fourier transforms infrared (FTIR), Scanning electron microscopy (SEM), Raman spectroscopy, differential scanning calorimetric (DSC), Scanning electron microscopy (SEM), the energy dispersive X-ray spectrometry (EDX) and UV spectroscopy.

To determine the transformation points, the obtained powdered xerogels were analyzed by Differential Scanning Calorimetry (DSC) using a SETARAM DSC–92 analyzer equipped with a processor and a measuring cell. The thermal cycle applied consists of heating from room temperature to 520°C, holding for 5min at this temperature and finally cooling back to room temperature with the same rate (5°C/min). X-ray powder diffraction was performed by Siemens D5005 diffractometer using a Cu Kα radiation. The patterns were scanned at room temperature, over the angular range 10-70° 2θ with a step length of 0.1° 2θ and counting time of 1 s.step⁻¹. The UV absorption studies were carried out using UV-VIS double–beam spectrophotometer SHIMADZU (UV3101PC). Its useful range is between 190 and 3200 nm. The treatment of the spectra was performed using the UVPC software.

A surface profiler DEKTAK 3ST AUTO1 (VEECO) was used to determine film thicknesses. Raman spectra were recorded in a back scattering configuration with a Jobbin Yvon micro Raman spectrometer coupled to a DX40 Olympus microscope. The samples of doped and undoped TiO₂ thin films were excited with a 632.8 nm wavelength with an output of 20 mw.

3. Results

3.1. Solution properties

3.1.1. Viscosity

This part is devoted to study the effect of solution aging and its viscosity on the films thickness. To do this study, five samples are developed, successively on the day, the next day, after seven days, after 10 days, and after fourteen days of solution synthesis. The conservation of the sol during the 14 days is made at room temperature.

Table 1 shows an important change of layers thickness with the increasing of the solution viscosity. After a repose period of 14 days of synthesis solution doped with ZrO₂, the thickness of layer changes from 32 nm, with a viscosity 10 mPa.s, to 81 nm when the viscosity is 180 mPa.s. We notice that the ZrO₂-doped TiO₂ solution becomes more viscous over time (Figure 1). This reflects the rate of polycondensation reaction progress.

Synthesis, Characterization and Properties of Zirconium Oxide (ZrO$_2$)-Doped Titanium Oxide (TiO$_2$) Thin Films Obtained via Sol-Gel Process

3.2. Powder Properties (Xerogel)

3.2.1. X-Ray Diffraction (XRD)

Figure 2a and b shows the X-ray diffraction (XRD) patterns of TiO$_2$ xerogels of undoped (Figure 2a) and 5% ZrO$_2$-doped TiO$_2$ (Figure 2b). The XRD pattern evolution of titanium xerogel obtained after the evaporation of the organic compounds during 3 months of aging at ambient temperature shows that it is an amorphous phase as reported in [54].

It has been reported that the used acid catalyst, during sol–gel preparation, plays a crucial role for determining the TiO$_2$ phase, in literature [54, 55], they found that powder is amorphous when they use acetic acid as catalyst. However, when using formic acid they found that, in addition to amorphous phase, there is an amount of the anatase nanoparticles. This analysis of the doped TiO$_2$ xerogel exhibits that the addition of 5% ZrO$_2$ (Figure 2b) would be largely sufficient to form nanoparticles of anatase which crystallizes with (101) plane. It is interesting to note that the addition of a minor amount of ZrO$_2$ starts crystallization of anatase. Whereas, A. Kitiyanan et al. [56] B. Neppolian et al. [57] reported that addition of ZrO$_2$ has no effect on TiO$_2$ oxide morphology..
3.2.2. Thermal analysis

The differential scanning calorimetric (DSC) curves of undoped TiO\textsubscript{2} and 5% ZrO\textsubscript{2}-doped TiO\textsubscript{2} xerogels are shown in Figure 3. It is interesting to note that both doped and undoped xerogels showed a similar thermal behavior in the temperature range 20–250 °C. Generally, weight loss corresponds to the evaporation of water, thermal decomposition of butanol as well as carbonization or combustion of acetic acid and other organic compounds [58-60] which constitute metal alkoxides. Hence, the above thermal events were represented by an endothermic peak spreading from 50 to 250 °C.

A double exothermic peak in the 260–450 °C temperature range of TiO\textsubscript{2} xerogel can be attributed to the crystallization of titanium oxide [61].

The addition of 5% of zirconium oxide led to a shift of exothermic peak phase towards lower temperatures. This may be due to the speeding up of the crystallization of titanium oxide compared to the undoped one.

Figure 2. Evolution of XRD patterns of xerogels (a) undoped TiO\textsubscript{2}, and (b) 5% ZrO\textsubscript{2}-doped TiO\textsubscript{2}.
3.3. Thin films properties

3.3.1. Structural Properties

3.3.1.1. Thin films thickness

The measured values of thin films thickness, given in Figure 4, were determined with a surface profiler for various layers and at different annealing temperatures. It is clearly observed that the film thickness increases with the number of dipping and annealing temperatures.
3.3.1.2. Study of deposition rate

A thin film deposited by dip-coating method has a thickness which can be controlled by the deposition rate. To simplify, d thickness depends on the speed according to the following relationship:

\[ d = k V_d^a \]

Where:

- \( V_d \) is the deposition rate,
- \( k \) is the empirical factor depending on the viscosity, surface tension and density of the solution used,
- \( a \) is the exponent with 2/3 value according to Landau and Levich [62], and 1/2 according to Michels et al. [63] or even proportionately at the speed of dipping Hewak et al. [64].

We then set the objective of determining this factor to validate one of these different models. So, we have prepared six samples with different deposition rate from 0.6 cm.s\(^{-1}\) to 2 cm.s\(^{-1}\) in the same conditions (deposited in solution with a viscosity 40 mPa.s at 21°C and treated at 400°C); we measured their thicknesses by profilometer and the results are grouped in table 2 and represented in figure 5.

This curve shows a linear increase in ln(d) versus ln(V_d). For the exponent a, values of 0.965 have been obtained, which is in good agreement with the exponent obtained by Hewak et al. [64]. This simple comparison shows that the increase in the speed of dipping, results an increase in the thickness of doped thin films.

3.3.1.3. X-Ray Diffraction (XRD)

3.3.1.3.1. Crystallization

a. Influence of annealing temperature

Our samples were analyzed using X-ray diffraction (XRD) to investigate the transformation behaviors. We have studied the structural properties of undoped TiO$_2$, and doped with 5% ZrO$_2$ thin films and deposited by the sol–gel method. The dip-coated thin films have been examined at different annealing temperatures (350 to 450 °C).

Figure 6 shows XRD patterns of 5% ZrO$_2$-doped TiO$_2$ thin film obtained after different dipping and treated at 450 °C. However, Figure 7 shows XRD patterns of 5% ZrO$_2$-doped TiO$_2$ thin film obtained after 2 dipping and treated at various annealing temperatures at 350 °C, 400 °C and 450 °C. Clearly, titanium oxide starts to crystallize starting from annealing at 350 °C.

This analysis of the doped TiO$_2$ thin films exhibits that the addition of a minor amount of ZrO$_2$ would be largely sufficient to form 4 sharp diffraction peaks at 25.35°, 35.51°, 50.90°
and 60.76°, these are assigned to (101), (112), (200), and (105) planes which are attributed to anatase nanoparticles (crystalline) phase of TiO$_2$.

Furthermore, all XRD patterns show a peak at 30.41° corresponding to (111) plane which is attributed to the brookite formation whatever the annealing temperature.

Peak intensities corresponding to characteristic planes of anatase (101) and brookite (111) phases are obviously increased with the increase of annealing temperature and number of dipping. This latter is interpreted as due not only to increase in proportion of titanium oxide but also to the improvement of the crystalline quality.

However, in the same conditions Kitiyanan et al. [56] B. Neppolian et al. [57] showed that titanium oxide, crystallizes in anatase phases and they found that addition of minor amount of ZrO$_2$ has not contributed to any change in the TiO$_2$ morphology.

b. Influence of doping with ZrO$_2$

Comparison between XRD patterns (Figure 8) of both undoped and doped with 5% ZrO$_2$ thin films obtained after 2 dippings and annealed at 400 °C temperature showed a similar behavior, so characteristic peaks correspond to the crystallization of anatase and brookite phases of the doped state is shifted to larger angles compared to the undoped one.

![Figure 6](image.png)

*Figure 6.* Evolution of diffraction patterns of 5% ZrO$_2$-doped TiO$_2$ thin films; obtained after various dipping (2, 4, 6, 8) annealed at 450°C. •: substrat, ◆: anatase, ◇: brookite.
Synthesis, Characterization and Properties of Zirconium Oxide (ZrO$_2$)-Doped Titanium Oxide (TiO$_2$) Thin Films Obtained via Sol-Gel Process

3.3.1.3.2. Surface morphology and grain size

The crystallite size $D$ of TiO$_2$ doped with ZrO$_2$ thin films can be deduced from XRD line broadening using Scherrer equation [65]:

**Figure 7.** Evolution of diffraction patterns of 5% ZrO$_2$-doped TiO$_2$ thin films; obtained at various annealing temperatures (350, 400, 450 °C) for the same thickness.

**Figure 8.** Comparison between undoped and 5% ZrO$_2$-doped TiO$_2$ diffraction patterns.
\[
D = \frac{0.94 \times \lambda}{\sqrt{\left(\Delta_{hkl}^2 - \Delta_{\text{instr}}^2\right)}} \times \frac{1}{\cos \theta}
\]

\(\lambda\) is the wavelength of X-ray beam (Cu \(K_\alpha = 1.5406\,\text{Å}\)), \(\Delta_{hkl}\) is the full width at half maximum (FWHM) of \((hkl)\) diffraction peak, \(\Delta_{\text{instr}}\) is the FWHM corresponding to the instrumental limit, and \(\theta\) is the Bragg angle.

Using the size of the crystallites, the dislocation density \(\delta\) \[66\], the number of crystallites per unit surface area \(N\) and strain in the films \(\varepsilon\), which are newly introduced by Ray et al. \[66\], has been determined:

\[
\delta = \frac{1}{D^2}
\]

\[
N = \frac{d}{D^3}
\]

\[
\varepsilon = \frac{\Delta(2\theta) \cdot \cos \theta}{4}
\]

Where \(d\) is the film thickness.

The calculated structural parameters are presented in Table 3.

**Table 3.** Structural parameters of xerogels and thin films, for different annealing temperatures and same thickness.
The computed values of grain sizes, given in Table 3, were calculated for different annealing temperatures with the same thickness. Thus, the obtained grain sizes of anatase and brookite increase from 8.58 nm to 20.56 nm and from 17.50 nm to 18.06 nm, respectively. In fact, as annealing temperature increases grain sizes also increases.

It is interesting to note that the grain size improves and the defects like dislocation density and strain in the films decrease with film thickness. This may be due to the improvement in crystallinity in the films with film thickness. As we also note that the variation of the strain is perfectly correlated with that of the dislocation density $\delta$. When these increase, they cause the decrease in grain size and leads to recrystallization of the nanoparticles. Furthermore, the stages of nucleation, growth and coalescence become stable, which causing the reduction of constraints in the film formed.

The evolution of the grain size $D$ according the annealing temperature can be interpreted by the Arrhenius law (figure 9):

$$D = D_0 \exp \left( -\frac{E_a}{k_B T} \right),$$

Where:
- $E_a$ is the energy activation of crystallization;
- $K_B$ the Boltzmann constant;
- $D_0$ pre-exponential factor.
- The size $D$ tends towards the infinite for high temperatures [67].

The values of activation energies of crystallization corresponding respectively to anatase and brookite phases are calculated from the curve showed in figure 9, we note that the activation energy of the anatase $E_a=0.096$ eV crystallization is lower than that of the brookite $E_a=0.012$ eV. This means that the formation of anatase requires more energy than that of brookite.

3.3.1.4. RAMAN

The Raman spectra of undoped and 5% ZrO$_2$-doped TiO$_2$ thin films annealed at 450°C for different dipping (figure 10) display various peaks related to titanium oxide as anatase and brookite phases. These spectra exhibit bands at around 138 (strong), 235 (weak), 514 (weak) and 632 cm$^{-1}$ (medium)) for the thin layers of ZrO$_2$-doped TiO$_2$ corresponding to the Eg modes of vibration. The above bands can be assigned to anatase phase except the band 235 cm$^{-1}$ corresponding to the B1g modes of vibration, which is due to the crystallization of brookite phase. While bands of 144, 188 and 651 cm$^{-1}$ can be assigned to both anatase and brookite phases [68,69].

A slight shift of the most intense peak, Eg, to smaller wavenumber is observed for all thin films doped with ZrO$_2$ by comparison with anatase of undoped phase (figure 11). Similar displacements have been previously reported in XRD patterns and they can be correlated with the confinement effects in nano-structured anatase crystallites.
Figure 9. Plot of log (D) versus (1000/T) for determination of activation energies of anatase and brookite

- $E_a$ (anatase) = 0.096 eV
- $E_a$ (brookite) = 0.012 eV
Figure 10. Raman spectrum of 5% ZrO$_2$-doped TiO$_2$ thin films annealed at 450°C for different dipping; ■=anatase, ●=brookite.

Figure 11. Comparison between Raman spectrum of undoped and 5% ZrO$_2$-doped TiO$_2$ thin films; ■=anatase, ●=brookite.
3.3.1.5. FTIR

Figure 12 shows the infrared absorption spectrum of the 5% ZrO$_2$-doped TiO$_2$ films annealed at different temperature. The peak at 2360 cm$^{-1}$ resulted from the adsorbed H$_2$O molecules, which were not removed completely after sol–gel coating. The peaks at 1242 cm$^{-1}$, 1111 cm$^{-1}$, 1035 cm$^{-1}$ and 860 cm$^{-1}$ correspond to the vibration mode of Ti-OH [70, 71].

The band around 665 cm$^{-1}$ was attributed to the vibration mode of Ti-O-Ti bond [72] and another bond appears around 455 cm$^{-1}$, this is the O-Ti-O band corresponding to the crystalline titania in the anatase form [73-76].

We find that the vibration bands intensity located in the vicinity of 665 cm$^{-1}$ and 455 cm$^{-1}$ increase when annealing temperature increases. This indicates that the number of Ti-O-Ti and O-Ti-O links of titanium dioxide crystallization is also growing.

![Figure 12. FTIR spectra of 5% ZrO$_2$-doped TiO$_2$ thin films, obtained at various annealing temperatures (350, 400, 450 °C).](image-url)
3.3.1.6. Scanning electron microscopy (SEM) and EDX

5% ZrO₂-doped TiO₂ thin films deposited on ITO substrates and obtained after various annealing temperature at 350°C and 450°C were coated and examined in a scanning electron microscope (SEM) to investigate their structure and surface characteristics. We observed that the coating was homogeneous without any visual cracking over a wide area. The increase in the treatment temperature, did not affect the uniformity of the film.

The surface composition of films is further identified by EDX measurement. EDX result shown in Figure 13 demonstrates that the peaks of Ti, O and Zr can be clearly seen in the survey spectrum. While the other elements as Si, In, Ca, Na and Mg are the components of ITO substrate.

The chemical compositions of thin film analyzed are given in table 4.

3.3.2. Optical properties

3.3.2.1. UV absorption analysis

Figure 14 display diffused scattering UV-VIS transmittance spectra of TiO₂ thin films undoped and 5% ZrO₂-doped TiO₂, for different annealing temperatures from 350°C to 450°C and different numbers of dipping (3, 4, 6, 8 dipping) in the wavelength range 300–800 nm, where the film due to interference phenomena between the wave fronts generated at
the two interfaces (air and substrate) defines the sinusoidal behavior of the curves’ transmittance versus wavelength of light. The curves showed a similar behavior in the temperature range:

- A region characterized by a strong absorption at $\lambda < 380$ nm, this absorption is due to the transition electronic inter-band.
- High transmittance region, from 60 to 95% on a wide range of wavelength in the visible region (from 380 to 800 nm) has been observed which may be used in applications in solar cells. High transparency is one of the most important properties that explain the interest in undoped or doped TiO$_2$ thin films.

As can be seen, all the spectrums exhibit interference fringes, which are due to the multiple reflections at the two film edges, i.e. at the film/air and the film/substrate interfaces. This indicates that the top film surface is smooth and uniform and exhibits a good transparency in the visible region. So that the excellent surface quality and homogeneity of the film were confirmed from the appearance of interference fringes in the transmission spectra. This occurs when the film surface is reflecting without much scattering/absorption in the bulk of the film.
If the film surface is rough, the radiation in film/air interface undergo scattering in all directions instead of a reflection. Oh et al. [28], Kim et al. [77] show that the interference fringes are due the increase in thin films thickness. The occurrence of such fringes means that our films are sufficiently thick.

Analysis of UV–VIS transmission spectra shows that the 5% ZrO$_2$-doped TiO$_2$ thin films are transparent in the visible range and opaque in the UV region, whatever are the annealing temperature and number of dipping.

The amplitude of interference spectra increased with increasing calcination temperature. These results show that the refractive index of TiO$_2$ thin films is increased while the film thickness is decreased. This can be due to the formation stage of anatase and with the increase in the grain size [28].

A slight shift of transmission curves to lower wavelengths is observed for curves of ZrO$_2$-doped thin films in comparison with those undoped (figure 14) This shift is ascribed to the increase in band gap energy.

3.3.2.2. Refractive index, density, thickness and porosity

The refractive index of TiO$_2$ thin films was calculated from measured UV–VIS transmittance spectrum. The evaluation method used in this work is based on the analysis of UV–VIS transmittance spectrum of a weakly absorbing film deposited on a non-absorbing substrate [78]. The refractive index $n(\lambda)$ over the spectral range is calculated by using the envelopes that are fitted to the measured extreme:

$$n(\lambda) = \sqrt{S + \sqrt{S^2 - n_0^2(\lambda)n_s^2(\lambda)}}$$

$$S = \frac{1}{2}(n_s^2(\lambda) + n_0^2(\lambda)) + 2n_0n_s\frac{T_{\text{max}}(\lambda) - T_{\text{min}}(\lambda)}{T_{\text{max}}(\lambda) \times T_{\text{min}}(\lambda)}$$

Where $n_0$ is the refractive index of air, $n_s$ is the refractive index of the film, $T_{\text{max}}$ is the maximum envelope, and $T_{\text{min}}$ is the minimum envelope. The thickness of the films was adjusted to provide the best fits to the measured spectra. In this study, all the deposited films are assumed to be homogeneous.

The porosity of the thin films is calculated using the following equation [79]

$$\text{Porosité} = \left(1 - \frac{n^2 - 1}{n_d^2 - 1}\right) \times 100(\%)$$

Where $n_d$ is refractive index of pore-free anatase ($n_d = 2.52$) [80], and $n$ is refractive index of porous thin films.
The relationship between density, and refractive index for the polymorphs was proposed by Gladstone-Dale [81]. This relationship is as follows:

\[ n = 1 + 0.4\rho \]

Where:
- \( n \): mean index of refraction,
- \( \rho \): density
- 0.40: Gladstone-Dale constant for TiO\(_2\)

The thickness of the films was calculated using the equation:

\[ d = \frac{\lambda_1\lambda_2}{2} \left( \frac{\rho_1 - \rho_2}{n_1 - n_2} \right) \]

Where \( n_1 \) and \( n_2 \) are the refractive indices corresponding to the wavelengths \( \lambda_1 \) and \( \lambda_2 \), respectively [82].

The results of the computed refractive index (\( n \)) (figure 15), density (\( \rho \)) and porosity (\( p \)) (figure 16) are shown in Table 5. It is noted that the refractive index and the density of thin films of doped titanium oxide increases with increasing annealing temperature and number of dipping; due to phase transition (anatase, anatase–brookite), which increases grain sizes and/or the density of layers.

This phenomenon is related to crystallization, pores destruction and densification of associated film, as well as the elimination of organic compounds.

However, the porosity decreases with increasing annealing temperature and film thickness.

**Table 5.** Variation of refractive index (\( n \)), density (\( \rho \)), porosity (\( p \)) of undoped and 5\% ZrO\(_2\)-doped TiO\(_2\) for different annealing temperatures and different thickness.

The calculated values of thin films thickness are given in table 6. It is clearly observed that the film thickness increases with the number of dipping and annealing temperatures, which is in good agreement with results obtained previously of thickness determined with a surface profiler.

3.3.2.3. Optical band gap:

The band gap is then found as the intercept of the linear portion of the plot. For a direct band gap semi-conductor, the absorption near the band edge can be estimated from the following equation known as the Tauc plot [83]:

\[
(\alpha \nu) = C (\nu - E_g)^n
\]

Where \(C\) is a constant, \(E_g\) the optical band, \(\alpha\) is the optical absorption coefficient, \(\nu\) is the photon energy gap, \(h\) the Plank’s constant and the exponent \(n\) characterizes the nature of band transition; the values of \(n = 1/2\) and \(3/2\) correspond to direct allowed and direct forbidden transitions, \(n = 2\) and \(3\) are related to indirect allowed and indirect forbidden transitions [83] and in the cases for a direct band gap semi-conductor like TiO\(_2\) the relation become [84, 85]:

\[
(\alpha \nu)^2 = C (\nu - E_g)
\]

The energy band gap \(E_g\) of the films can be estimated by plotting \((\alpha \nu)^2\) versus \(\nu\) (Figure 17), then extrapolating the straight-line part of the plot to the photon energy axis. The energy band gap of 5% ZrO\(_2\)-doped TiO\(_2\) films, given in table 7, decrease owing to an increase in annealing temperatures and the number of dipping. The values are 3.65 and 3.54 eV at 350°C and 450°C respectively.

This decrease was correlated with grains size increases with temperature, when the latter increases the defects and impurities tend to disappear causing a reorganization of the structure. We find that doping with ZrO\(_2\) causes an increase in the band gap by contrast to that of undoped TiO\(_2\) (3.50 eV).

Table 7. Variation of band gap of 5% ZrO\(_2\)-doped TiO\(_2\) thin films for different annealing temperatures and different thickness.
4. Conclusion

In this study, we investigated the transformation behaviors and the effect of a smaller ratio range of ZrO$_2$; doping on the surface area of TiO$_2$ thin films, band gap energy, variations of crystal granularity, phase composition and especially on the evolution of the crystallite size and defects concentration with annealing treatments and layers thickness of the samples produced. So that in this chapter, we report the study of structural, thermal and optical properties of ZrO$_2$-doped TiO$_2$ thin films deposited by the sol–gel process.

Analyses of doped TiO$_2$ xerogel show that addition of 5% ZrO$_2$ would be largely sufficient to form nanoparticles of anatase (size of grain of 14.78 nm) by contrast to that of undoped TiO$_2$. X-ray diffraction and Raman spectroscopy analyses exhibit that doped thin films obtained starting from annealing at 350°C crystallize in both anatase and brookite phases. Calculation of grain sizes by Scherrer’s formula, gives sizes ranging from 8.58 to 20.56 nm and we note an increase in grain sizes by increasing the annealing temperature for all structures. Raman spectroscopy studies confirms the results found by XRD and reveal that
the films annealed from 350 to 450°C crystallizes in anatase and brookite structure. From the DSC analysis, we have demonstrated that an annealing temperature equal or higher than 340 °C for undoped and 260 °C for 5% ZrO₂-doped would be sufficient to form titanium oxide. The addition of 5% of zirconium oxide led to a shift of exothermic peak phase towards lower temperatures, due to the speeding up of the crystallization of titanium oxide compared to the undoped one.

Analysis of UV-VIS transmission spectra shows that the 5% ZrO₂-doped TiO₂ thin films are transparent in the visible range and opaque in the UV region, whatever the annealing temperature and the number of dipping. Refractive index of the thin films of titanium oxide increases with increasing annealing temperature and number of dipping, but the porosity decreases, due to phase transition (anatase, anatase–brookite), which increases grain sizes and/or density of layers. Energy band gap of 5% ZrO₂-doped TiO₂ films decease owing to an increase in annealing temperatures, also we find that doping with ZrO₂ causes an increase in the band gap by contrast to that of undoped TiO₂.

The optical properties of the films are found to be closely related to the microstructure and crystallographic structure which depend on the annealing temperature. In summary, In this study, we successfully fabricated ZrO₂-doped TiO₂ thin films, with desired structural and optical properties by sol–gel dip coating using the titanium alkoxide (tetrabutyl-orthotitanate) as a starting material.
