Chapter

Introductory Chapter: Silicon

Beddiaf Zaidi and Slimen Belghit

1. Introduction

Silicon (Si) is a member of Group 14 (IV\text{A}) in the periodic table of elements. Si is also part of the carbon family. This family elements include C, Ge, Sn, and Pb. Silicon is a metalloid, one of only a very few elements that have properties of both metals and non-metals. Si is the second most abundant element in the Earth's crust, apart from oxygen.

2. Energy bands

Silicon is a semiconductor whose number of free electrons is less than conductor but more than that of an insulator. Two kinds of energy band which are conduction and valence. Series of energy levels having valence electrons forms valance band in solid. At 0\textdegree K, the energy levels of valence band are filled with electrons. This band contains maximum of energy when the electrons are in valence band. Conduction band is the higher energy level band, which is the minimum of energy. Conduction band is partially filled by the electrons, which are known as the free electrons as they can move anywhere in solid. These electrons are responsible for current flowing. There is a gap of energy. The difference between the conduction band and valence band is called energy gap. For semiconductors, the gap is neither large nor the bands get overlapped (Figure 1).

3. Basic material

Apart from the oxygen, silicon is most commonly occurring element on the Earth. Silica is the dioxide from silicon and occurs mostly as quartz. Its synthesis has been familiar for many decades. It is extracted from (mainly) quartzite reduction with carbon in an arc furnace process [1]. The pulverized quartz and carbon are put in a graphite crucible. An arc causes them to melt at approximately 1800\textdegree C. Then, the reduction process takes place according to the formula:

\[
\text{SiO}_2 + 2\text{C} \rightarrow \text{Si} + 2\text{CO} \quad (1)
\]

The liquid collected at the bottom of crucible can then be drawn off. Its purity can be approximately 97.9\%. This is called metallurgic grade silicon (MG-Si). However, for silicon to be used in the semiconductor industry, the impurities must be removed almost completely by further processes. For such a high purity grade, multistage processes must be implemented.
4. Silicon thin film

Silicon thin-film cells are mainly deposited by chemical vapor deposition (typically plasma-enhanced, PE-CVD) from silane gas and hydrogen gas. Depending on the deposition parameters, these silicon thin films can be based on one or a combination of these materials [2–5]:

1. Amorphous silicon (a-Si or a-Si:H) or polymorphous silicon
2. Microcrystalline silicon
3. Polycrystalline silicon (poly-Si).

These silicon thin film materials can be characterized by their grain sizes ranging from none (amorphous) to large silicon (~100 μm) for polysilicon. The crystalline silicon thin films present dangling bonds, which result in deep defects (energy levels in band gap) as well as deformation of the conduction and valence bands. The solar cells made from thin films tend to have lower energy conversion efficiency than silicon bulk but are also less expensive to produce (Table 1).

Table 1. Grain size range depending on the type of the silicon [6–8].

5. Application

Silicon materials are used in components of electronic devices. It is also used to make solar cells [9–13] and parts for computer circuits [14]. Solar cell is a device
that converts sunlight into electrical energy [15–23]. A rectifier is an electrical
device that converts alternating current to direct current. The most important
silicon alloys are those made with Fe, Al, and Cu. When silicon is produced, in fact,
scrap iron and metal are sometimes added to the furnace [24, 25].
