Climate Change Impacts and Adaptation Strategies for Agronomic Crops

Ishfaq Ahmed, Asmat Ullah, M. Habib ur Rahman, Burhan Ahmad, Syed Aftab Wajid, Ashfaq Ahmad and Shakeel Ahmed

Abstract

Climate change is a serious threat to agriculture and food security. Extreme weather conditions and changing patterns of precipitation lead to a decrease in the crop productivity. High temperatures and uncertain rainfall decrease the grain yield of crops by reducing the length of growing period. Future projections show that temperature would be increased by 2.5°C up to 2050. The projected rise in temperature would cause the high frequent and prolong heat waves that can decline the crop production. The rise in temperature results in huge reduction in yield of agronomic crops. Sustaining the crop production under changing climate is a key challenge. Therefore, adaptation measures are required to reduce the climate vulnerabilities. The adverse effect of climate change can be mitigated by developing heat tolerant cultivars and some modification in current production technologies. The development of adaptation strategies in context of changing climate provides the useful information for the stakeholders such as researchers, academia, and farmers in mitigating the negative effects of climate change.

Keywords: climate change impacts, climate change projections, adaptation strategies

1. Introduction

Climate change and variability are the real threats to agriculture and food security [1, 2]. Extreme weather events and uncertainty in rainfall patterns are negatively affecting the agricultural crops [3, 4]. The evidences of global trend in rainfall are unclear due to large regional gaps in spatial coverage and temporal shortfalls in the data. Owing to these changes, the drought is more prevailing in many regions of the world including Pakistan [5]. Finding evidences reported that high temperature and uneven distribution of rainfall have negative effects on crop productivity all over the world [6]. These changes in weather and climate are likely to affect the food security of developing world where a large fraction of ever-increasing population is already fronting hunger, insecure and unhealthy food [7]. Warming of weather and climate systems can
Climate Change and Agriculture

results in highly corresponding changes in the occurrence of extreme events including rise in temperature, uneven rainfall patterns [4]. These extreme events occur due to shift in their distribution, or to change in the shape of distribution. Various studies suggest that a shift in mean accounts for much the change in observed temperature extremes [8]. Comparisons of various studies showed that both daily maximum (Tmax) and minimum (Tmin) temperatures have shifted toward higher values in all regions. These shift in temperatures and rainfall significantly affected the cropping patterns, crop yields and phenology [9].

The Intergovernmental Panel for Climate Change (IPCC) has found evidences of accelerated global warming, climate variability and change since the early 1990s. The IPCC reported that average global temperature in the last 100–150 years has increased by 0.76°C [10]. The variability in temperature altered the phenology of crop, i.e., leaf development, anthesis, harvest, fruit production and in asynchrony between anthesis and pollinators. The variable temperature range resulted in high respiration rates, reduction in pollen germination, shorter grain filling period, lesser biomass production and low yields [4]. High temperature above 35°C in combination with high humidity and low wind speed caused a 4°C increase in temperature, resulting in floret sterility in cereals and fruits [6]. Climate change impact assessment provides the scientific foundation for the development of adaptations to offset the negative impacts of climate change. Keeping in views, the current study was planned to assess the impacts of climate change and adaptations strategies for agronomics crops.

2. Projections of climate change across the globe especially in ASIA

World faces dreadful challenges due to changing climate as it is indicated by climatic models that global surface temperature is likely to exceed 1.5°C relative to 1850–1900 for all representative concentration pathways (RCP) scenarios for the end of the twenty-first century [11]. It is likely to exceed 2°C for RCP 6.0 and RCP 8.5 and warming will continue beyond 2100 under all RCP scenarios. Increase of global mean surface temperatures for 2081–2100 relative to 1986–2005 is projected to likely be increased 0.3–1.0°C (RCP 2.6), 1.1–2.6°C (RCP 4.5), 1.4–3.1°C (RCP 6.0), 2.6–4.8°C (RCP 8.5) by the of the twenty-first century. It is projected that temperature would increase drastically in arid areas of Pakistan and India and western part of China [11]. Models predictions indicated that erratic rainfall with greater intensity would increase across the region, but higher intense rainfall will occur during summer monsoon season. Increase in aridity in South and Southeast Asia is projected due to decline in winter rainfall. Sea level will rise to 3–16 cm by 2030 and 7–50 cm by 2070 across the globe due to climatic abnormalities and in relation with regional sea level variability [11].

It is evident from the facts that lives of millions rural poorest people in Asia are highly vulnerable to climate change. There are evidences of prominent increase in intensity and frequency of many extreme events such as heat waves, erratic and uncertain rainfall patterns and more number of hot days, sustained dry spells, tropical cyclones and dust storms in the region. These countries accounted for 91% of the world’s total death and 49% of the world’s total damage due to natural disasters in the last century. South Asia is the most food insecure region with 262 million malnourished people in the world [6, 12]. Discussed facts showed (Table 1) that rural communities that already live in remote dry lands and deserts with inadequate natural resources are most prone to climate change. Agricultural systems being affected by abnormal climatic variables that disturbs the biological, physical and chemical processes of the systems. Number of hot days and warm nights are likely

3. Impact of climate change on crop production

Global atmospheric concentrations of greenhouse gases have significantly increased relative to pre-industrial times [13, 39, 40]. As a result, greenhouse gas forcing is the main cause of the warming of the atmosphere during the past decades [14, 41, 42]. This warming is expected to substantially alter the climate system and change global food production, mainly because temperatures are predicted to increase which in turn will alter the precipitation pattern and increase the frequency of extreme events such as drought [15, 43–45]. Man-made greenhouse gas emissions as a result of industrialization and urbanization have made significant

Table 1. Impact of climate change on cereal crop production.

To increase in the Asia from 1961 to 2003 and reduction in cool days and nights was observed especially in the years after the start of El Nino [37]. Tropical cyclones frequency and intensity has increased in Pacific from last few decades [38].
Climate Change and Agriculture

contributions to global warming and further changes in the global climate. As a result, global temperature rose by 0.83°C from 1906 to 2010 [10]. Global warming also causes changes in precipitation levels and patterns due to higher evapotranspiration and water vapor amounts in the atmosphere with several implications for the global hydrological cycle [16, 46]. As the major water consumer of the developing world and some developed countries, agriculture is one of the most vulnerable water sectors to climate change [17, 18]. Dramatic population growth, associated with reduction of productive land area and water resources, exerts extra pressure on the agricultural sector. To ensure sustainability of agriculture, studying the possible climate change impacts on this sector is essential [9, 19, 47].

Rate of plant growth and development is dependent upon the temperature surrounding the plant and each species has a specific temperature range represented by a minimum, maximum, and optimum [48–50]. The expected changes in temperature over the next 30–50 years are predicted to be in the range of 2–3°C Intergovernmental Panel for Climate Change [10]. Heat waves or extreme temperature events are projected to become more intense, more frequent, and last longer than what is being currently observed in recent years [51, 52]. Extreme temperature events may have short-term durations of a few days with temperature increases of over 5°C above the normal temperatures [53]. Extreme events occurring during the summer period would have the most dramatic impact on plant productivity. A recent review by Barlow et al. [54] on the effect of temperature extremes, frost and heat, in wheat (*Triticum aestivum* L.) revealed that frost caused sterility and abortion of formed grains while excessive heat caused reduction in grain number and reduced duration of the grain filling period. Analysis by [55] revealed that daily minimum temperatures will increase more rapidly than daily maximum temperatures leading to the increase in the daily mean temperatures and a greater likelihood of extreme events and these changes could have detrimental effects on grain yield. If these changes in temperature are expected to occur over the next 30 years then understanding the potential impacts on plant growth and development will help develop adaptation strategies to offset these impacts [56, 57].

Previous studies of climate change impacts on agriculture, using crop yield simulation models [9, 58–60] or statistical models suggest that climate change will substantially affect productivity of major staple food crops such as maize, because growth and development of crops are mainly dependent on sunlight, temperature, and water [22, 23, 61]. Climate change may modify precipitation, soil water, runoff, and may reduce crop maturation period and increase yield variability and could reduce areas suitable for the production of many crops [24, 62, 63]. Climate change might limit crop production (the amount of a crop that is harvested in a farm, region, state, or country in kilograms or tons) in many areas [64–66].

Temperature increases affect most plants, leading to crop yield reduction and complex growth responses [25, 46, 67]. Nevertheless, the impact of increasing temperatures can vary widely between crops and regions. For example, a 1°C increase in the growing period temperature may reduce wheat production by about 3–10% [68], winter wheat productions may be decreased by 5–35%, respectively, under the future warmer and drier conditions [21, 26], and corn yield may be reduced by 2.4–45.6% due to higher temperatures [27, 69]. Even if precipitation is unchanged, the crop production may decrease by 15% on average due to the reduction in crop growth period and increased water stress as the result of higher temperature and evapotranspiration (Schlenker et al. [63]; Yang et al. [16]; Khanal et al. [28]) expected precipitation reductions in arid and semiarid regions of the world, where water is already limited, can have dramatic impacts on crop production [32–35]. For example, in northwestern Turkey, winter wheat yield may decline more than 20% under future climate change because the growth periods can be shortened as a result
of increased temperature, exacerbated by a reduction in precipitation [21, 29–31]. Higher reduction in wheat yield of 50% was found in Pakistan as shown in Table 2. In some other areas, climatic change might have positive influences on agricultural crop yield, i.e., in dry areas rainfall enhances under wet climatic warming can lead to improved crop productions like in Mexico the wheat yield would be increase by 25% in future (Table 2). Maize, rice, winter wheat and potato crop yield can be enhanced with increasing air temperature and rainfall in the Plain of North China [73]. In Ghana maize yield would be increase by 12% in future (Table 2). The impact of climate change on sugarcane and cotton is shown in Table 3. Higher reduction in cotton yield of 17% and sugarcane yield of 40% was found at USA (Table 3). However, some positive impacts of climate change on sugarcane yield were found in few countries such as Brazil and Australia (Table 3). The impact of climate change on coarse grain, oilseed and other miner crops such as pearl millet, sorghum and sesame are shown in Table 1. Huge reduction in coarse grain and other

Table 3. Productivity shock due to climate change on rice, wheat, and coarse grains by 2030.
crops were found in China up to 2030. However, higher losses in oilseed crops were observed at India and Pakistan as shown in Table 1.

4. Adaptation strategies for agronomic crops

Climate change adaptation is the action to global warming, which helps to reduce the vulnerabilities in the social and biological system. The main objective of adaptation strategy is to build the resilient in societies against climate change [74].

Agriculture sector is highly vulnerable to changing climate. Extreme weather conditions and changing patterns of precipitation affects the crop development, growth and yield of crops. High temperature at critical growth stages could reduce the grain filling duration caused the grains sterility and consequently yields reduction. [4]. To avoid the risks in agriculture associated with climate change (CC), adaptation is the key factor that could help to mitigate the negative of climate change. Adaptation strategies provide an opportunity to address the CC challenges and to sustain the crop production [75].

In the recent year, climate change adaptation has been explored by the farmers in many ways. For example, in Pakistan and Brazil farmers has adapted the climate change variability by adjustment of planting time and optimization of plant populations [9, 60]. Adjustment of planting date is important to explore the fully potential of crop. High temperature at grain filling stage, reduce the time for grain filling that lead to decrease the yield. Adjusting the planting time with the onset of rains and heat waves would decrease the yield losses. Number of plants per unit area plays a vital role for higher yield in crops especially wheat. The number of productive tillers dies or remains unproductive due to variation in temperature and moisture stress. The optimum plant population compensates the yield loss. The development of improved varieties such as early maturing, drought and heat tolerant are necessary to

Table 4. Climate change adaptations for agronomic crops.
sustain the productivity under changing climate. The new cultivars would increase
the production per unit area under moisture stress and extreme temperatures [76].

Methane gas is produced form the flooded rice. Flood water in rice blocks the
oxygen to penetrate in soil that creates the favorable condition for bacteria that emit
the methane gas. So new methods of planting like direct seeded rice and system of
rice intensification with Alternate wetting and draying reduce the methane emis-

ion and increase the water use efficiency [77].

Precision management of nutrients can increase the resilience in the crops by
increasing the efficiency of fertilizers. Precision management of fertilizers in crops
especially maize reduced the use of fertilizers that would enhance the production
and soil health that lead to decrease the emission of greenhouse gases (GHGs)
[78]. Ratoon crop of sugarcane is more adaptive to climatic vulnerabilities. Fuel
consumption is less for tillage practices, and less soil is disturbed that lead to reduce
the GHGs emission. Pit planting is new evolutionary method in sugarcane. In this
methods sugarcane seedling are grown in a small pit under field condition. This
method improved the aeration and solar radiation that lead to increase the qual-
ity of cane juice and number of canes for milling [79]. Weeds are serious issue in
the chickpea cultivation. Weeds compete with the chickpea plants for water and
nutrients that reduce the growth and yield of chickpea. So integrated weed control
improves the yield. GHGs emissions are also reduced due to less use of synthetic
weedicides [80] (Table 4).

5. Conclusion

Climate change and variability have negative effects on crop productivity. Change in precipitation pattern, increase in frequency, and intensity of extreme
events such as heat waves and drought have detrimental effects on grain yield.
Future projections showed that temperature would be increased by 2–3°C at the
end of century. Number of hot days and warm night will be increased in Asia and
high intense rainfall will occur in summer monsoon. This warming situation would
cause a huge reduction in grain yield of crops by end of century. Wheat yield is
expected to decrease by 50% in Pakistan, maize yield by 46% in China, cotton yield
by 17% in USA and sugarcane yield would reduce by 30% at India. The negative
effects of climate change can be mitigated by developing some adaptation measures.
The development of heat tolerant cultivars, modification in current production
technologies of crop can offset the negative effects of climate change. In future,
climate change impacts should be studies by using low and high emission scenarios
for early, mid and late century. The adaptation strategies should be quantified based
on modeling approaches.
